General introduction on von Willebrand Factor

List of abbreviations

a.u.	asymmetric unit
CR	Complement receptor
CD	Cluster of Differentiation
EC	Endothelial Cells
iC3b	inactivated Complement 3b
ICAM	Intercellular Adhesion Molecule
LFA-1	Leukocyte Function-associated Antigen 1
LRR	Leucine-rich repeat
Mac-1	Macrophage antigen alpha polypeptide-1
MIDAS	Metal Ion Dependent Adhesion Site
TTP	Thrombotic Thrombocytopenic Purpura
VCAM-1	Vascular Cell Adhesion Molecule-1
VLA	Very Late Antigen
VWF	von Willebrand Factor
vWFcp	von Willebrand Factor cleaving protease, also known as ADAMTS13
ADAMTS	A Disintegrin And Metalloprotease with Thrombospondin Motives

Chapter 1 Introduction

Discovery of Von Willebrand Factor

In 1926 the Finnish Internist [Eric A. von Willebrand](#) reported a case of patients from the Åland Islands with “hereditary pseudohaemophilia”¹. Elongated bleeding and clotting times were manifested. It was not real haemophilia, because both male and female were affected. In 1953 it was found that patients with von Willebrand Disease also lacked factor VIII. In 1972 von Willebrand Factor was purified and the protein was sequenced by Edman degradation in 1986². The [cDNA](#) was cloned and sequenced in 1985^{3; 4}. The last decades, von Willebrand factor (vWF) is intensively studied and slowly the secret of its action becomes clear.

Normal haemostasis is dependent on vWF

Haemostasis can be divided in two different processes, i) staunching, which is the process that stops the bleeding due to the formation of a platelet plug and ii) coagulation, which is the process of fibrin formation that stabilises the platelet plug. Coagulation is dependent on the presence of coagulation proteins, calcium and the negatively charged phospholipid phosphatidyl serine. The latter two compounds are provided by platelets that become adhered at the site of vascular damage. Platelet plug formation is dependent on von Willebrand Factor and adhesive compounds from the vascular matrix⁵.

Upon damage of the vessel wall, contents of the vessel wall are exposed to the blood. *In vitro* it has been shown that vWF can bind to fibrillar collagen types I, III and IV⁶. *In vivo*, however, vWF is co-localised with collagen types I, III and VI in the subendothelium^{7; 8} and not with collagen type IV⁹. When vWF is immobilised to the subendothelium, it can bind to platelet glycoprotein (Gp) Iba α via its A1 domain¹⁰. The interaction of the A1 domain with GpIba α has relative high association- and dissociation rate constants, thereby preventing permanent arrest of the platelet¹¹⁻¹³. In other words, the platelets tether and or roll over the surface. However, tethering platelets do slow down via interactions of platelet receptor GPVI with collagen¹⁴. Due to the interaction of GPVI with collagen, the platelet becomes activated (the activation process involves many signal transduction pathways and will not be discussed here) that results in binding of integrin $\alpha_2\beta_1$ to collagen and binding of integrin $\alpha_{2b}\beta_3$ to the RGD sequences of fibrinogen and vWF¹⁵. The latter event results in platelet-platelet interactions leading to platelet plug formation. The adhered platelets spread, release their granular contents (calcium, ADP and coagulation factors) and the negatively charged phospholipid

phosphatidyl serine becomes exposed. Now coagulation starts and the thrombus obtains its final strength.

Biosynthesis of vWF

The vWF gene is located on [chromosome 12p13.3](#) and spans approximately 178 kilo basepairs. It contains 52 exons which code for 2813 amino acid residues^{2; 4}. A pseudogene is located on [chromosome 22q11.1](#), is 21-29 kbp in length and spans exons 23-34¹⁶. The overall homology between the vWF gene and pseudogene is 96.9 %. There is slight divergence between the sequences corresponding to the exons (97.5 %) and slightly more divergence for the introns (96.8 %).

VWF is synthesised as pre-pro-vWF in megakaryocytes¹⁷ and endothelial cells (EC)^{18; 19}. After synthesis, the 22 amino-acid residues of the vWF pre-peptide are cleaved off in the endoplasmatic reticulum, vWF is dimerised at the C-terminus and partially glycosylated^{20; 21}. VWF-dimers are transported to the Golgi apparatus and multimerisation takes place in the trans Golgi network²². Sorting to the Golgi-apparatus does not require the propeptide, also known as vWF-Ag II²³, whereas multimerisation does²⁴. For multimerisation the propeptide does not have to be covalently linked to the protein²⁵. The protease furin cleaves the pro-peptide but the peptide remains non-covalently associated with mature vWF^{22; 26}. Any uncleaved propeptide is removed from the multimer in the plasma, but the enzyme responsible for this process remains unknown²⁷. Additional *N*-linked and *O*-linked glycosylation^{28; 29} and sulfation²² occurs. VWF is *N*-glycosylated at asparagine residues 94, 384, 468, 752, 811, 1460, 1527, 1594, 1637, 1783, 1822 and 2027. *O*-linked glycosylation sites are threonine residues 485, 492, 493, 705, 714, 724, 916 and 1535 and serine 500 and 723².

After synthesis, vWF is partitioned between two pathways. Approximately 95 % is constitutively secreted. The remainder is stored in the tubular structures in α -granula of megakaryocytes²⁹ and in Weibel-Palade bodies of endothelial cells^{29; 30}. Weibel-Palade bodies are not formed in vWF deficient cells, whereas α -granula are still present, but these granula lack the tubular systems³¹. Sorting of vWF to storage granules requires the propeptide, and Arg⁴¹⁶ has been shown to be essential^{23; 32}. This implies that the propeptide functions as a catalyst in multimerisation and as a molecular chaperone in translocation to storage granules. The stoichiometry of the propeptide and mature vWF is 1:1 in the Weibel-Palade bodies.

In vivo, vWF and propeptide plasma levels are 10 and 1 $\mu\text{g/ml}$, respectively. Half-lives are 12 h and 2 h, respectively³³. VWF plasma levels depend on the blood group³⁴. Blood group AB persons have an average plasma level of 12.2 $\mu\text{g/ml}$, blood groups A and B 10.6 $\mu\text{g/ml}$ and blood group O 8.8

µg/ml. Propeptide levels are not blood group type sensitive, because the propeptide does not contain the A and B oligosaccharides whereas mature vWF does^{35; 36}. Increased plasma levels can result from stimulation of endothelial cells by for example 1-desamino-8-D-arginine vasopressin (DDAVP)³⁷.

Functional domains of mature vWF

Mature, monomeric vWF consists of 2050 amino acid residues in twelve domains (figure 1)³⁸. VWF multimerises upto 80 monomers in a multimer³⁹. The D3 domain contains cysteins that form the N-terminal intermolecular disulfide bridges. Intermolecular disulfide bridges are formed involving Cys³⁷⁹⁻⁴⁰, and at least one cysteine of triplet Cys⁴⁵⁹-Cys⁴⁶²-Cys⁴⁶⁴^{40; 41}. The CK domain, residues 1961 – 2050, contains cysteins that are involved in C-terminal intermolecular disulfide bridges probably requiring Cys²⁰⁰⁸, Cys²⁰¹⁰ and Cys²⁰⁴⁸⁴². Intra-molecular disulfide bridges are formed between Cys¹⁹⁶¹-Cys²⁰¹¹, Cys¹⁹⁸⁷-Cys²⁰⁴¹, Cys¹⁹⁹¹-Cys²⁰⁴³ and Cys¹⁹⁷⁶-Cys²⁰²⁵ within the CK domain⁴². The D' and the D3 domains are involved in binding clotting factor VIII⁴³⁻⁴⁵ thereby preventing factor VIII from binding to membrane surfaces and activation and degradation by a variety of serine proteases⁴⁶. Factor VIII binding affinity decreases when vWF is bound to collagen⁴⁷. The A1 domain binds GpIbα¹⁰, heparin¹⁰, collagen type III and VI^{8; 48-50} and sulfatides⁵⁰⁻⁵². The linker between the A1 and A2 domains is involved in binding to leukocytes⁵³. The A2 domain contains the proteolytic cleavage site for the vWF protease⁵⁴. The A3 domain contains the collagen binding site^{48; 55}. No specific function has been assigned for the D4 and B domains. The C domains contain the recognition sequence RGD at residues 2507-2509, which bind to platelet integrin α_{2b}β₃⁵⁶. The vWF multimeric structure is essential for its function^{57; 58}. In collagen binding, multimeric vWF displays an apparent K_d of 1 – 7 nM⁵⁹, while monomeric, recombinant A3 binds collagen with a K_d of 2 µM⁶⁰. In contrast, factor VIII binding only requires N-terminal dimers.

Figure 1: Schematic representation of the pre-pro-vWF domain organisation. Scissors indicate sites where vWF is cleaved during synthesis (before Ala²³ and Ser⁷⁶⁴) or in plasma in the A2 domain (after Tyr¹⁶⁰⁵) by the vWFcp. Of note, the diagram is not on scale.

A-type domains

A-type domains (and homologous integrin I- or inserted domains) are recognized in vWF A1, A2 and A3 domains, integrins of the β_1 family, $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_{10}\beta_1$, $\alpha_{11}\beta_1$, integrins of the β_2 family, $\alpha_L\beta_2$, $\alpha_X\beta_2$, $\alpha_M\beta_2$, integrins α_D , $\alpha_E\beta_7$, different collagen subtypes, complement components ⁶¹ and other proteins. A brief summary of A type domains is given in Table I and figure 2.

A-type domains adopt a so-called Rossman or di-nucleotide binding fold that consists of a central hydrophobic β -sheet, flanked on both sides by amphipathic α -helices (figure 3). The top face consists of loops connecting the α -helices and the β -strands and contains the metal-ion-dependent-adhesion-site (MIDAS) motive. The MIDAS motive will be discussed below. The bottom face consists of loops connecting the α -helices and the β -strands and contains a disulfide bridge.

Table I
vWF domains and integrin receptors containing A- or I-type domains

Receptor	Alternative name(s)	Ligand(s)	References
vWF-A1		GpIb α , collagen type III and VI, botrocetin, ristocetin, heparin, sulfatides, bitiscetin	10; 41; 62-66
vWF-A2		vWFcp	67; 68
vWF-A3		collagen type I and III, bitiscetin	55; 69
$\alpha_1\beta_1$	VLA-1, CD49a/CD29	collagen, laminin-1	56; 70
$\alpha_2\beta_1$	VLA-2, GpIa/IIa, CD49b/CD29	collagen I and III	56; 71-75
$\alpha_{10}\beta_1$		echovirus, laminin-1	76
$\alpha_{11}\beta_1$		collagen II	56; 77
$\alpha_D\beta_2$	CD11d/CD18, ADB2, leuointegrin alpha D	VCAM1	78
$\alpha_E\beta_7$	CD103, mucosal lymphocyte-1 antigen	E-Cadherin	56

Figure 2: Alignment of vWF-A and integrin-I domains. The domains were pre-aligned using ClustalW 1.81 at the EBI website (<http://www.ebi.ac.uk/clustalw/>). Alignments of domains with known crystal structures were optimised based on a superposition of the models. The alignment of domains with unknown crystal structure were adjusted to the crystal-structure optimised alignment. Residues in *Bold* form the MIDAS motive, α -helices and β -strands are indicated by the *dark* and *blue* boxes, respectively.

Figure 3: Structure of the A- or I-type domains. The vWF-A1 domain is shown. A-type domains contain a so-called dinucleotide binding or Rossmann fold that consists of a central β -sheet which is flanked on both sides by α -helices (colour coded in *red* and *blue*, respectively). The top- and bottom faces contain loops connecting the α -helices and β -sheet. The bottom-face contains the disulfide bridge and in integrin I-domains the top face contains the MIDAS motif. In the vWF-A1 domain vWD type 2B mutations cluster at the bottom of the domain and vWD type 2M mutations scatter all over A1.

A1 domain

The vWF-A1 domain spans residues 509 – 695 and contains the GpIb α binding site^{10; 41; 63}. The crystal structure has been solved^{83; 84}. It binds to GpIb α ¹⁰, collagen^{48 48; 64}, ristocetin⁶⁶, botrocetin⁶⁵, bitiscetin⁸⁵, sulfatides⁵⁰⁻⁵² and heparin^{10; 50; 86}. The sulfatide- and heparin-binding sites probably do not overlap⁵². The N- and C-termini are linked by a disulfide bridge. The formation of this disulfide bridge is an absolute requirement for a proper function of the vWF-A1 domain. In the absence of the disulfide bridge, the GpIb α binding affinity is strongly reduced⁸⁷⁻⁹⁰. Moreover, the function of the A1 domain is modulated by the number of residues in the N- and C-terminal peptides⁹¹ and the presence of *O*-linked glycans. The number of residues in the flanking peptides required for a proper modulation of the A1-domain is still a matter of debate (table II). Removal of the *O*-linked glycans^{89; 92} or desialisation⁹³ pro-activates the A1 domain. The antibiotic ristocetin A and the snake toxins botrocetin and bitiscetin bind to specific sequences in A1 resulting in activation of A1.

The A1 domain does not bind spontaneously to GpIb α , therefore it needs to be activated. Activation can be achieved via vWF-immobilisation to a surface (for example the vessel wall), although it is not clear whether activation occurs due to a conformational change in vWF or because the local vWF-concentration is increased. Additionally, vWF can be activated due to vWD type 2B mutations and activators like ristocetin or botrocetin and will be discussed below. The structure of the A1•GpIb α complex and conformational changes in the A1 domain that result in GpIb α binding are the subject of chapters five and six of this thesis.

Table II
Effect of the length of the N- and C-terminal flanking peptides on the activation-state of A1

Construct	Origin	Effect in GpIb binding	References
plasma vWF	human	No spontaneous binding to GpIb, ristocetin and botrocetin activate binding	
441-730	CHO/COS-7	No spontaneous binding to GpIb, ristocetin activates	94; 95
481-718	human	No spontaneous binding to platelets, ristocetin and botrocetin activate	87
481-718 Δ sialic acid	human	Bit spontaneous binding to platelets, ristocetin does not activate, botrocetin activates	87
475-709	COS-7	No spontaneous binding to GpIb, ristocetin activates	89
441-704	<i>E. coli</i>	Little bit spontaneous binding to platelets, botrocetin activates	96
475-709	<i>E. coli</i>	No spontaneous binding to GpIb, less ristocetin required for activation	89
508-704	<i>E. coli</i>	Binds spontaneous to platelets, less platelets bind to A1-coated surface at high shear stress and the platelets that become attached to the surface do not tether	90
508-733	<i>E. coli</i>	Spontaneous binding to platelet, botrocetin activates	96

A2 domain

Defining the borders of the A2 domain is not straightforward, because the A2 domain does not contain a disulfide bridge connecting the N- and C-termini. Based on sequence homology with other A-type domains, we define the borders between residues Ser⁷³¹ and Cys⁹⁰⁷ (figure 2). The A2 domain contains the cleavage site for the [von Willebrand Factor cleaving protease](#) (vWFcp) that is also known as ADAMTS13^{54; 97; 98}. The gene for the vWFcp is located on [chromosome 9q34](#). This enzyme cleaves the A2 domain between residues Tyr⁸⁴² and Met⁸⁴³ resulting in lower vWF multimers^{99; 100}. The A2 domain contains a disulfide bridge at the bottom of the domain, but this disulfide bridge does not connect the N- and C-terminal flanking peptides. The disulfide bridge is formed between two consecutive residues. The aberrant disulfide bridge is essential, because otherwise a proteolytic cleavage within the A2 domain does not decrease the multimeric size of vWF.

A number of mutations in the A2 domain (and also some in the A1 domain), so-called vWD type 2A mutations, have been identified in patients that make vWF more sensitive towards the vWFcp¹⁰¹. Most likely, these mutations partially unfold the A2 domain thereby making the A2 domain more susceptible to the protease. As a result, these patients lack the high-molecular-weight multimers in their plasma. The partial unfolding (or sensitisation) of vWF is probably required for efficient proteolysis for several reasons. i) Based on homology with other A-type domains it is most likely that the Tyr⁸⁴²-Met⁸⁴³ peptide bond is located in the interior of the domain (figure 4), ii) *in vivo* application of shear increases the proteolysis¹⁰², iii) *In vitro* low ionic strength buffers and denaturing agents are required for proteolysis¹⁰⁰. A deficiency in vWFcp-activity results in the presence of ultra-large vWF multimers that may cause [thrombotic thrombocytopenic purpura](#) (TTP), which is manifested by thrombocytopenia, microangiopathic hemolytic anemia, bleedings and other symptoms¹⁰³.

Figure 4: Model of the A2 domain. This hypothetical model of the A2-domain has been constructed based on the homologous vWF-A1 domain (PDB accession code 1auq), which, based on amino-acid sequence, is the most closely related A-type domain and has been prepared by the internet 3dpssm server (<http://www.sbg.bio.ic.ac.uk/servers/3dpssm>). Of note, the connectivity of the model is not complete, which is most significant for helix $\alpha 4$ that is absent in A2. Strand $\beta 2$ is drawn transparent for clarity. The von Willebrand Factor cleaving protease cuts between residues Tyr⁸⁴² and Met⁸⁴³, which are shown in ball-and-stick representation and are located at the centre of the β -sheet in the interior of the domain.

A3 domain

The A3 domain spans residues 923 to 1109 and contains the binding site for fibrillar collagen types I and III^{55; 60}. The multimeric structure of vWF is important for vWF binding to collagen. The K_d of monomeric A3 and multimeric vWF for the binding to collagen is 2 μ M and 4 nM, respectively^{59; 60; 104}. Crystal structures have been solved by two groups independently^{105; 106}. The putative vWF-A3 MIDAS motif at the top-face of A3 is formed by residues Asp⁹³⁴, Ser⁹³⁶, Ser⁹³⁸, Ser¹⁰⁰⁵ and Thr¹⁰³⁸ (figure 2). The latter two residues are threonine and aspartic acid in I-domains. In A3 however, the aspartic acid (Asp¹⁰³⁹) has been shifted by one residue and the hydroxyl group of Thr¹⁰³⁸ is not able to coordinate to the metal ion. In addition, the side chain of Asp¹⁰³⁹ (which is glycine in the case of integrin I-domains) prevents a metal-ion from entering the MIDAS motive. The MIDAS motif of integrin I-domains usually contains a magnesium or manganese ion^{75; 79; 82; 107} which is absolutely required for ligand binding¹⁰⁸⁻¹¹⁰. The MIDAS motif of A3 does not contain a metal-ion and the binding of A3 to collagen type I and III is metal-ion independent^{105; 106; 111}.

The collagen-binding site of integrin α_2 I-domain, and most likely also of the I-domain of integrins $\alpha_1\beta_1$ ⁷⁰, $\alpha_{10}\beta_1$ ⁷⁶, $\alpha_{11}\beta_1$ ⁷⁷, is located at the top-face of the domain^{74; 112}. A divalent cation, either Mg²⁺ or Mn²⁺^{108; 109}, bound to the MIDAS motif is involved in collagen binding^{71; 74} and the protruding additional helix determines the specificity towards certain collagen subtypes^{75; 113}. The top face of the vWF-A3 domain is not involved in collagen binding^{59; 106; 114} and therefore the collagen-binding site on A3 must be located somewhere else. Two other studies on the collagen-binding site were conducted. Cruz *et al.* constructed an A1/A3 chimera, spanning residues 475-598/1018-1114¹⁰⁴. Collagen binding of this chimera was similar compared to wt-A3. Based on a cyanogen bromide digestion of vWF, Roth *et al.* localized a collagen-binding site within residues 948-998. An additional collagen binding site, however, was identified within residues 542-662 in A1⁴⁸ suggesting that the collagen binding affinity of the A1/A3 chimera may also originate from residues 479-598 of the A1 domain. The exact location of the collagen-binding site in the A3 domain is the subject of chapters two, three and four of this thesis.

The nature of the collagen triple helix interacting with vWF has been studied by Verkleij *et al.*¹¹⁵. A collagen type III related-peptide from the α_1 chain containing residues 541 – 558 (in sequence GAA GRP* GPP* GSA GTP* GLQ (P* = hydroxyproline)) was able to bind vWF directly. However, in a perfusion system platelets also adhered to a collagen-related-peptide spanning residues 511 – 540 in a vWF dependent manner. This discrepancy was also observed for collagen type IV that does not bind vWF directly, but platelet adhesion to a collagen type IV coated surface is vWF dependent^{55; 62; 116}. In analogy to the α_2 I-domain, it seems likely that vWF binds to multiple collagen sequences with different affinities⁷⁰.

Glycoprotein Ib-IX-V complex

The glycoprotein Ib-IX-V complex contains the proteins GpIb α , GpIb β , GpIX and GpV in stoichiometry 2:2:2:1 (figure 5) and it is the platelet receptor for vWF, α -thrombin, P-selectin and $\alpha_M\beta_2$ (reviewed in ¹¹⁷ and ¹¹⁸). Approximately 20,000 copies of the complex are present per platelet. GpIb α associates covalently with GpIb β outside the cell via a disulfide bridge close to the transmembrane helices of both proteins. GpIb β non-covalently associates with GpIX ¹¹⁹. Via GpIb α , two GpIb α -GpIb β -GpIX trimers associate non-covalently with one GpV molecule. Within the cell, GpIb-IX-V associates with actin-binding protein, phosphatidylinositol 3-kinase ¹²⁰ and the signalling protein 14-3-3 ζ ^{120; 121}. It has been hypothesised that upon vWF- or thrombin-binding to the GpIb-IX-V complex, 14-3-3 ζ delivers phosphatidylinositol 3-kinase to the cytoskeleton ¹²⁰ and thereby keeps integrin $\alpha_{2b}\beta_3$ in its phosphorylated, active conformation ¹²². All extra-cellular members of the GpIb-IX-V complex contain so-called leucine-rich repeats (LRRs). GpIb α and GpV contain a heavily glycosylated stalk. The glycosylated stalk of GpIb α is extremely long and positions the vWF binding-site at 45 nm from the platelet surface. Expression of the GpIb α -GpIb β -GpIX trimeric complex at the platelet membrane requires all three components, whereas GpV is not required ¹²³. Impaired expression of the GpIb-IX-V complex results in a not well developed demarcation membrane of megakaryocytes resulting in giant platelets and low platelet numbers ¹²⁴. It has been suggested that GpV enhances the avidity of the GpIb-IX complex and thereby strengthens the interaction of vWF with the platelet ¹²⁵. GpV also binds to collagen type I ¹²⁶.

Figure 5: Model of the GpIb α -Ib β -V-IX complex. At the platelet surface, GPIb α is disulphide-linked to GPIb β that is associated in a non-covalent manner with GPIX. GPIb α is also non-covalently associated with GPV. The stoichiometry of the complex is 2:2:2:1. All members of the complex are linked to the platelet membrane via a transmembrane helix. O- and N-linked glycosylation sites are indicated by circles and squares, respectively. (adapted from Berndt *et al.* ¹¹⁸)

GpIb α contains the vWF-binding site. The binding site is located in the N-terminal 293 residues of the GpIb α that contains several distinguishable domains:

- Residues 1-35: N-terminal flanking sequence.
- Residues 36-200: seven leucine-rich repeats (LRRs).
- Residues 201-268: double-loop- or C-terminal flanking sequence.
- Residues 269-282: anionic region.

It is not clear whether the N-terminal flanking sequence interacts directly with A1, because botrocetin induced vWF binding is not dependent on this loop whereas the loop appears to be involved in ristocetin-induced vWF binding ¹²⁷.

Leucine-rich repeats, which are found in numerous proteins involved in hormone-receptor interactions, enzyme inhibition and cell adhesion processes (reviewed in ¹²⁸), contain 20-29 amino-acid residues repeating sequences. The LRRs of the GpIb-IX-V complex belong to the “typical” LRR subfamily with the repeating sequence LxxLxxLxLxxN/CxLxxLpxxoFx-x, in which “x” is any residue, “o” is any non-polar residue and “-” is a possible insertion site. Within a protein the different LRRs typically contain the same number of residues. An alignment of LRRs from human GpIb α is given in figure 6A. A LRR forms a “U”-shaped structure in which one leg is a β -strand and the other leg a helical structure (figure 6B). The type of helical structure depends on the type of protein; in ribonuclease inhibitor it is an α -helix, in internalin B it is a 3_{10} -helices and in U2B’-U2A’ it contains α -helices, 3_{10} -helices and short loops ¹²⁸. A number of consecutive LRRs form a horseshoe-like structure, with on the inner-face a parallel β -strand and on the outer-face the helical structures that determine the curvature of the horse-shoe. Conserved asparagine (or cysteine) residues at the base of the LRR form hydrogen bonds with the preceding LRR. The parallel β -strands and the β - α loops form the interaction surface with other proteins, although sequences outside the LRRs may contribute in ligand binding ¹²⁸. The LRR is flanked on both sides by structures that protect the hydrophobic core of the “U”-shaped structure. These flanking sequences are typically amphipathic α -helices or cysteine-rich structures.

Figure 6: The GpIb α leucine rich repeats. A: The GpIb α leucine rich repeats were aligned using the program ClustalW 1.81 and adopts the consensus sequence of the so-called "typical" sub-family of LRR-proteins, except for the phenylalanine residue after the non-polar residue that is absent in LRRs 1-6. Residues that form the β -strand and helical-like structure are underlined and in *bold*, respectively. The indicated numbering starts at the ATG of the 16-residue signal peptide. B: The seven GpIb-LRRs form a horseshoe like structure¹²⁹. GpIb α -LRR 5 (see chapter 5 of this thesis) is shown as a typical example. Residues that form the β -strand and α -helix are colour-coded *red* and *blue*, respectively.

The LRRs of human, canine and mouse GpIb α have been modelled using the known crystal structure of internalin B¹²⁹. The inner face of the hypothetical GpIb α -LRRs model contain β -sheets, whereas the outer face most likely contains 3_{10} helices. It has been suggested that the LRRs interact with the vWF-A1 domain for several reasons. Firstly, LRRs in other proteins are known to form a structural framework required for protein-protein interactions¹²⁸. Secondly, human vWF does not bind to GpIb α containing canine GpIb α LRRs 2-4¹²⁷. Thirdly, a number of Bernard-Soulier syndrome mutations are located in the LRRs (Table III). However, since these mutations involve buried residues in the hydrophobic core, these mutations most likely alter the conformation of the LRR that is most likely the underlying cause of the observed reduced A1 binding.

The double-loop domain is essential for the interaction with A1. Its function has been investigated in only one, recent study¹³⁰. It contains two disulfide bonds between Cys²⁰⁹-Cys²⁴⁸ and Cys²¹¹-Cys²⁶⁴. It has been proposed that the first disulfide loop and its N-terminal flanking peptide up to residue Phe²⁰¹ interacts with LRR-6 and this interaction is required for proper binding to A1. Disruption of this interaction results in a loss-of-function phenotype. All platelet-type vWD mutations are located in the first disulfide loop. The second disulfide loop is required for the interaction of botrocetin but not ristocetin with GpIb α . These findings confirm the hypothesis that ristocetin and botrocetin do not share the same binding-site on GpIb α . Replacement of the second double-loop by canine sequences results in a gain-of-function phenotype. The second disulfide loop

of human and canine differ only at five residues; charge alternations at positions Asp249Val, Asp252Lys, Lys253Asn, Lys258Thr and Gly263Asp. The mechanism by which these mutations activate GpIb α is not understood.

The anionic region contains ten aspartic and glutamic acid residues and three sulphated tyrosines at positions 276, 278 and 279. Although no consensus sequence exists for sulfation, negative charged residues at both sides of the tyrosines are required for a proper sulfation¹³¹. When the tyrosines are not sulfated, shear induced rolling of platelets over vWF or ristocetin- or botrocetin induced binding of vWF to GpIb α are strongly reduced^{125; 132; 133}. Interestingly, mutation of the tyrosines to glutamic acid abolishes botrocetin induced vWF binding, but does not have an effect in ristocetin-induced vWF binding and shear-induced rolling of cells. This suggests that just negative charges are satisfactory for ristocetin- or shear induced binding¹³³. Neutralising or charge reversal mutations of the negatively charged aspartic and glutamic acid residues in the anionic region decreases botrocetin- and ristocetin induced binding^{134 131}. The negative charges between residues 251-279 are essential for both ristocetin- and botrocetin induced binding, whereas the negative charges between residues 280-302 are also required for botrocetin induced vWF binding¹³⁴.

Modulators of the collagen–vWF–GpIb α axis

In vitro vWF functions can be influenced by several modulators. A number of molecules have been described that interfere with the binding of vWF to collagen or to GpIb α . These modulators act either by a loss-of-function or a gain-of-function mechanism (Table IV).

Table IV
Modulators of the collagen-vWF-GpIb α axis

Modulation	Modulator	Isolated from	Family	Function	Reference
Gain-of-function	Ristocetin	<i>Nocardia lurida</i>	antibiotics	activates A1	174-176
	Botrocetin	<i>Bothrops jararaca</i>	C-type lectin	activates A1	177-179
	Jararhagin	<i>Bothrops jararaca</i>	metalloproteinase-desintegrin	activates A1	180
	Bitiscetin	<i>Bitis arietans</i>	C-type lectin	activates A1 but binds to A1 and A3 domain	69; 85; 181; 182
	Jaracetin	<i>Bothrops jararaca</i>	metalloproteinase desintegrin	activates A1	180
Loss-of-function	Heparin		poly glycan	blocks A1	50; 86; 183; 184
	Flavocetin-A/B	<i>Trimeresurus flavoviridis</i>	C-type lectin	Blocks GpIb	185-187
	Alboaggregin-B		C-type lectin	Blocks GpIb	188
	Mamushigin	<i>Agkistrodon halys blomhoffii</i>	C-type lectin	Blocks GpIb	189
	Agkistatin	<i>Agkistrodon acutus</i>	C-type lectin	Blocks GpIb	190
	Echicetin	<i>Echis carinatus</i>	C-type lectin	Blocks GpIb	191-193
	Jararaca GpIb-BP	<i>Bothrops jararaca</i>	C-type lectin	Blocks GpIb	194; 195
	Tocaracetin	<i>Trimeresurus tokarensis</i>	C-type lectin	Blocks GpIb	196
	Heparin		glycosamineglycan	Blocks A1	86; 184
	Aurintricarboxylic acid			Blocks A1	197

These modulators belong to the C-type lectin super-family (although they do not possess lectin activity), metalloproteinase desintegrin family, glycopeptide antibiotics or aromatic chemical compounds. Botrocetin and ristocetin-A are relevant to the work described in this thesis and will be described in more detail.

Botrocetin

Botrocetin belongs to the C-type lectin super-family¹⁷⁹. It is a hetero-dimeric molecule containing a 133 amino-acid (15 kDa) α -subunit and a 125 amino-acid (14.5 kDa) β -subunit, each containing three intra-chain disulfide bonds and one inter-chain disulfide bond. Also a one-chain botrocetin variant (32 kDa) has been isolated, but this variant is less active in vWF activation and belongs to the metalloproteinase desintegrin family¹⁷⁸. The crystal-structure of botrocetin has been solved (figure 7)¹⁹⁸. A large loop protrudes from each of the subunits and interacts with its

counterpart. One magnesium ion is bound to the α -chain of the botrocetin heterodimer. A distinctive negatively charged region at the centre of the molecule is hypothesized to interact with positive charges on A1. Binding of botrocetin to A1 does not introduce conformational changes within A1. Mutagenesis and crystallographic studies identified residues in helices $\alpha 4A$, $\alpha 4B$ and $\alpha 5$ of A1 that are essential for botrocetin binding^{199;200}. These residues are close to Lys⁵⁹⁹, which is involved in GpIb α binding, indicating that botrocetin binds close to the GpIb α binding site. Botrocetin also interacts directly with GpIb α , see above. It has been hypothesized that botrocetin binds to A1 and thereby provides additional surface that interacts with GpIb α ²⁰⁰.

Figure 7: Structure of A1 activator botrocetin. Botrocetin activates the vWF-A1 domain that leads to GpIb α binding. A: The botrocetin crystal structure is shown. The botrocetin α (pink) and β (green) chains tightly interact via a large protruding loop. B: Surface potential of botrocetin. Positive- and negative potentials are coloured blue and red, respectively. It is hypothesised that the major negatively charged surface at the centre of botrocetin interacts with positive charges on A1.

Ristocetin

Ristocetin-A belongs to the glycopeptide antibiotics. It contains a poly-tyrosine backbone in which the aromatic rings are linked to each other via ether bonds. It also contains several glycan residues (figure 8)¹⁷⁴. The glycan residues are probably essential for the activation of A1, because removal of rhamnose residues results in an inactive form of ristocetin¹⁷⁵.

The ristocetin-binding site on A1 is different from the botrocetin binding site¹⁷⁶. Based on peptide inhibition studies it has been suggested that residues Cys⁴⁷⁴-Pro⁴⁸⁸ in the N-terminal flanking peptide and residues Ser⁶⁹²-Pro⁷⁰⁸ in the C-terminal flanking peptide are involved in ristocetin binding^{176; 201}. A1 in which Pro⁷⁰²⁻⁷⁰³⁻⁷⁰⁴ were mutated could not be activated by ristocetin, suggesting that these residues are essential for ristocetin binding⁹⁴. In contrast to botrocetin,

ristocetin-induced vWF binding to GpIb α correlates with shear-induced binding²⁰². Ristocetin does not only bind to A1, but also interacts with GpIb α , see above.

Figure 8: Structure of A1 activator ristocetin. Ristocetin is a glycopeptidic antibiotic and is homologous to vancomycin. Most likely a ristocetin dimer binds to specific sequences within the N- and C-terminal flanking peptides at the bottom of A1 via its modified tyrosine backbone. There is some evidence that ristocetin also may bind to the N-terminal part of GpIb α . (adapted from J.P. Scott *et al.*¹⁷⁴)

Malfunction of the Von Willebrand Factor–GpIb axis

Von Willebrand Disease (vWD) is the most common inherited bleeding disorder and can be divided in three different subtypes¹⁰¹.

- Type I vWD refers to a partial quantitative deficiency of vWF.
- Type II vWD refers to a qualitative deficiency of vWF.
- Type III vWD refers to a total quantitative deficiency of vWF.

Type II vWD is divided in four subtypes.

- Type II A refers to a decreased platelet-dependent function, associated with absence of high molecular weight (HMW) multimers.
- Type IIB refers to an increased GpIb α affinity and are so-called gain-of-function mutations.
- Type IIM refers to a decreased GpIb α affinity, without absence of HMW and are so-called loss-of-function mutations.
- Type IIN refers to a decreased affinity for factor VIII.

An extensive database with all known mutations in the vWF gene available on the World-Wide-Web, <http://www.shef.ac.uk/vwf/>. A summary of vWD type IIB and 2M mutations, both found in patients and identified by site directed mutagenesis, is given in [appendix I](#).

Type 2B mutations are scattered throughout the A1 domain and its N- and C-terminal flanking peptides. In the three dimensional structure of A1 these residues are spatially close together and are located in a region at the bottom of the domain (figure 3). It is hypothesized that amino acid residues susceptible for vWD type 2B mutations involve interactions with the N-terminal flanking peptide⁸⁴. In contrast, type 2B mutation I546V induces a conformational change in hair-pin $\beta 2$ - $\beta 3$ as has been shown in a crystallographic study²⁰³.

Type 2M mutations scatter over the domain (figure 3). Several residues are buried and are essential for the conformation of the A1 domain. Mutation of these residues most likely results in a missfolded domain that is not capable to bind to GpIb α . Other residues causing type 2M vWD are solvent exposed.

Other bleeding disorders affecting the vWF-GpIb α axis occur in the GpIb-IX-V complex and are [platelet-type vWD](#) (gain-of-function)²⁰⁴, that consence mutations in the first loop of the GpIb α C-terminal flanking sequence, and [Bernard-Soulier syndrome](#) mutations²⁰⁵ (loss-of-function) (Table III).

Scope of the Thesis

Von Willebrand Factor is essential for platelet adhesion and thrombus formation. Mechanisms at a molecular level involved in this process are only partially understood. Therefore we conducted several studies in which we investigated i) the binding of the vWF-A3 domain to collagen, ii) the complex formation of the A1 domain with its platelet receptor GpIb α and iii) conformational changes that activate the vWF-A1 domain.

Chapters **two and three** describe the identification of the collagen-binding site in the vWF-A3 domain using a combination of protein crystallography and site-directed mutagenesis. We have identified the collagen-binding site at the front face of A3.

Chapter **four** concerns mutation Ser968Thr in the A3 domain that has been found in a patient. The effect of the mutation on collagen binding and platelet adhesion has been studied and the crystal structure of Ser968Thr-A3 has been solved. We suggest that the collagen-binding site of the vWF-A3 domain undergoes a conformational change upon collagen binding.

Chapter **five** describes the complex of the vWF-A1 domain with platelet receptor GpIb α . The structure explains at a molecular level the effect of vWD type 2B and 2M mutations that have been identified in patients. The results of this study may be of great interest in the development of anti-arterial thrombotic drugs.

Chapter **six** was conducted to identify conformational changes in the vWF-A1 domain that result in vWF to GpIb α binding. Six crystal structures of wt-A1 and gain-of-function mutant Arg543Gln-A1 were solved and compared to A1 in the A1•GpIb α complex. The structures suggest that the N and C-terminal flanking peptides shield the GpIb α binding site on A1. Shear stress or gain-of-function mutations change the conformation of the peptides that results in GpIb α binding.

1. (S) represents identified by scanning mutagenesis.
2. (Ab) indicates that a monoclonal Ab reacts less well with the mutant, suggesting that the mutation (partially) unfolds the domain.
3. Normal indicates an activity > 90 %, partial reduced between 75 % - 90 %, reduced between 25 % - 75 %, strong reduced indicates activity between 10 – 25 % and not active < 10 %.
4. Ristocetin induced platelet aggregation.

Summary

Von Willebrand factor (vWF) is a multimeric glycoprotein that mediates platelet adhesion and thrombus formation at sites of vascular injury. VWF functions as a molecular bridge between collagen and platelet receptor glycoprotein Ib. The major collagen-binding site of vWF is contained within the A3 domain, but its precise location is unknown. To localize the collagen-binding site, we determined the crystal structure of A3 in complex with a Fab fragment of antibody RU5 that inhibits collagen binding. The structure shows that RU5 recognizes a non-linear epitope consisting of residues 962-966, 981-997 and 1022-1026. Alanine-mutants were constructed of residues Arg963, Glu987, His990, Arg1016 and His1023, located in or close to the epitope. Mutants were expressed as fully processed multimeric vWF. Mutation of His1023 abolished collagen binding, while mutation of Arg963 and Arg1016 reduced collagen binding by 25 – 35%. These residues are part of loops $\alpha\beta 4$ and $\alpha 1\beta 2$ and α -helix 3, respectively, and lie near the bottom face of the domain. His1023 and flanking residues display multiple conformations in available A3-crystal structures suggesting that binding of A3 to collagen involves an induced-fit mechanism. The collagen-binding site of A3 is located distant from the top face of the domain where collagen-binding sites are found in homologous integrin I-domains.

Introduction

Platelet adhesion to damaged vessel walls is the first step in the formation of an occluding platelet plug, which leads to the arrest of bleeding during normal hemostasis. Platelet adhesion can also cause thrombotic complications such as the occlusion of atherosclerotic arteries¹. The multimeric glycoprotein von Willebrand factor (vWF)¹ plays an essential role in platelet adhesion under conditions of high shear stress^{2,3}. In this process vWF serves as a molecular bridge that links collagen exposed by the damaged vessel wall to glycoprotein Ib located on the platelet surface. Collagens that act as binding sites for vWF include types I and III in perivascular connective tissue and type VI in the sub-endothelial matrix^{3,4}.

Mature vWF consists of a 2,050 residue monomer that contains multiple copies of so called A, B, C and D-type domains and one CK (cystine knot) domain arranged in the order D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK^{1,3}. Disulfide-bond formation between N-terminal D3 domains and between C-terminal CK domains generates vWF multimers that consist of up to 80 monomers. The A1 domain contains the binding site for glycoprotein Ib⁵. The A3 domain (residues 920-1111) contains the major binding site for collagen types I and III⁶. The multimeric structure of vWF is essential for high-affinity collagen binding⁷. Multimeric vWF binds collagen with an apparent K_d of 1-7 nM⁸, while a recombinant A3 domain has a much higher K_d of 2 μ M⁹. Deletion of the A2 and D4 domains, that flank the A3 domain, or deletion of the A1 domain does not decrease collagen binding of multimeric vWF^{6,8}. These data show that a monomeric A3 domain contains a fully active collagen-binding site, the only requirement for tight binding to collagen being the presence of multiple A3 domains within one vWF multimer.

Integrin I-type domains are homologous to vWF A-type domains^{10,11}. I-domains of integrin α -chains α_1 , α_2 , α_{10} and α_{11} all possess collagen-binding sites. A crystal structure of the α_2 I-domain reveals binding of a collagen-like peptide to a groove in the surface of the 'top' face of the domain¹². This groove contains a so-called metal ion-dependent adhesion site (MIDAS)^{13,14} which engages a glutamate residue of collagen.

The location of the collagen-binding site in the vWF-A3 domain is not known. Crystal structures of A3 do not display a collagen-binding groove in the top face, instead, the surface of A3 is rather smooth^{15,16}. Although the MIDAS motif is partly conserved, binding of A3 to collagen does not require a metal ion^{17,18} and no metal ion is observed in crystal structures of A3. Moreover, point mutations in the MIDAS motif of A3 do not disrupt collagen binding^{8,16} showing that the motif is not involved in collagen binding, at all. Site-directed mutagenesis

studies of other residues in the top face of A3 have yielded conflicting results. Cruz *et al.*¹⁹ reported in abstract form that amino-acid substitutions D1069R, R1074D, R1090D and E1092R resulted in a 50% reduction in binding of monomeric A3 to collagen. Van der Plas *et al.*⁸, however, observed normal collagen binding of fully processed multimeric vWF containing mutations D1069R, D1069A or R1074A. In the same study, mutations V1040A/V1042A, D1046A and D1066A also displayed normal collagen binding, suggesting that the collagen-binding site of vWF-A3 is not located in its top face.

The crystallographic study presented here was conducted to provide new clues on the location of the collagen-binding site of the vWF-A3 domain. We determined the structure of the A3 domain in complex with a Fab fragment of monoclonal antibody RU5, which inhibits binding of vWF to collagen. Site-directed-mutagenesis of residues located in the epitope-region show that the collagen-binding site is located distant from the top face of A3.

Experimental procedures

Purification of vWF-A3 and RU5

Recombinant seleno-methionine (Se-Met) A3, comprising residues 920 to 1111 of human vWF, was expressed and purified as described before¹⁵. For production of monoclonal antibody RU5 (IgG_{2a}, κ) hybridoma cells were injected in mice and ascites fluid was collected (Eurogentec, Seraing, Belgium). IgG was purified on a protein G-Sepharose column and Fab fragments were generated using an ImmunoPure Fab Kit (Pierce, Rockford IL, USA). RU5-Fab was further purified with A3-affinity chromatography. For that end, 10 mg of A3 was irreversibly bound via its N-terminal histidine tag to cobalt(III)-iminodiacetate chelating Sepharose (Pharmacia Biotech, Uppsala, Sweden), according to a procedure described by Hale²⁰. RU5 Fab fragment was loaded onto the A3-affinity column, washed with PBS and subsequently eluted with 50 mM triethylamine solution (pH 10.0). Some aggregates were removed on a Superdex 75 HR 10/30 gel-filtration column (Pharmacia, Uppsala, Sweden). Running buffer was 10 mM Tris-HCl pH 8.0, 25 mM NaCl. Next, RU5-Fab was mixed with a twofold molar excess of (Se-Met) A3. The A3-RU5 complex was separated from excess A3 by gel-filtration chromatography. Dynamic-light scattering measurements on a Dynapro-801 DLS Instrument (Protein Solutions, Charlottesville VA, USA) indicated the presence of 69-kDa particles in agreement with an expected molecular weight of about 72 kDa of the complex between A3 and RU5.

Crystallization and Data Collection

Crystals of the (Se-Met) A3-RU5 complex were grown by hanging-drop vapor-diffusion at 4° C using a protein concentration of 15 mg/ml and a precipitant solution consisting of 13% (v/v) iso-propanol, 22% (v/v) 2-methyl-2,4-pentanediol (MPD) and 100 mM cacodylic acid pH 5.3. The crystal used for structure determination had a size of 0.1x0.1x0.2 mm³ and was equilibrated in a cryo-protectant solution consisting of 8% iso-propanol, 30% MPD, 100 mM cacodylic acid pH 5.3. X-ray diffraction data were collected on beam line BW7B of the synchrotron-radiation facility of the EMBL outstation (Hamburg, Germany) with a Mar345 imaging plate (Mar, Evanston IL, USA). Data reduction, merging and scaling were performed with DENZO and SCALEPACK²³. Diffraction-data statistics can be found in Table I. Diffraction of the A3-RU5 crystal was anisotropic. For structure determination, anisotropic B-factors were applied with SCALEIT and SFTOOLS²⁴ to correct for the observed anisotropy.

Table I
Diffraction-data and refinement statistics

Diffraction data

^a Data completeness is 100% between 29.9-2.56 Å resolution and drops to 51.5% between 2.56-2.03 Å resolution, due to anisotropic diffraction.

^b Numbers in parentheses indicate statistics for highest resolution shells.

^c $R_{\text{merge}} = \sum_h \sum_i |I_{hi} - \langle I_h \rangle| / \sum_h \sum_i I_{hi}$

^d An asymmetric unit contains three A3-RU5 complexes.

Structure Determination and Refinement

A self-rotation function calculated with POLARRFN²⁴ and the unit-cell volume suggested the presence of three A3-RU5 complexes in the asymmetric unit (a.u.) with a V_M of 3.3 Å³/Da and a solvent content of 63%. Initial attempts to solve the structure by molecular replacement failed. Therefore, a rather weak anomalous signal ($\langle \Delta F_{\text{ano}} / \sigma(F) \rangle = 1.18$) arising from the presence of Se-Met in A3 was used to locate Se sites from an anomalous Patterson map. Six Se sites could be assigned to Met947, Met998 and Met1097 of two A3 molecules on the basis of inter-atomic distances and the observed two-fold non-crystallographic symmetry (n.c.s). The positioning of two A3 molecules in the a.u. allowed further molecular replacement to proceed in a straightforward manner. A Fab-fragment of protein data bank entry [2MPA](#)^{25; 26} was oriented using the program AmoRe²⁷ followed by Patterson correlation refinement using CNS^{28; 29}. Cross translation functions calculated with CNS identified the position of three Fab-fragments. A third A3 molecule was placed on the basis of n.c.s. The a.u. finally contained three A3-RU5 complexes with an R-factor of 42.6% after rigid body refinement.

For model building, sequences of the constant domain of the light chain (C_L) and of the constant domain of the heavy chain (C_{H1}) of RU5 were taken from IgG_{2a, κ} monoclonal antibody 4-4-20^{30; 31}. The sequence of residues 1 to 110 of the V_L domain of RU5 (Fig. 1B) was derived from the electron density aided by a consensus sequence based on an alignment of 110 Fab sequences. For model refinement, cycles of rebuilding using O³² and positional and B-factor refinement using CNS were performed until convergence. Cross validation was used throughout refinement using a 5% test set of reflections. Refinement used the maximum-likelihood algorithm³³. Bulk-solvent correction and anisotropic scaling of diffraction data was applied. During the first cycles of refinement n.c.s. restraints were used. Based on the behavior of the free R-factor, n.c.s. restraints were omitted in later stages of refinement. Water molecules were placed in difference electron-density peaks with a peak height of at least 2.8 σ , a distance of 2.5-3.4 Å to a hydrogen-bond donor or acceptor and a B-factor smaller than 65 Å².

Construction of vWF Point Mutants

Point mutations were introduced in the vWF-A3 domain using the Quikchange method (Stratagene, La Jolla CA, USA) and specific primers (Amersham Pharmacia Biotech, Roosendaal, The Netherlands). First, a 518 base pair NheI-Csp45I fragment corresponding to amino acid residues 940 to 1113 of mature vWF was subcloned into pBluescript SKII (Stratagene, La Jolla CA, USA). To this end a unique Csp45I restriction site was introduced at position 5628 of

expression vector pNUT-vWFcas⁸ in the following way. The BamHI - EcoRV fragment of pNUT-vWFcas was ligated into pBluescript SKII. The Csp45I site was introduced using Quickchange and confirmed by sequencing. The NheI – EcoRV fragment containing the new Csp45I site was ligated into pNUT-vWFcas generating pNUT-vWFcas2. Next, the NheI - Csp45I fragment of pNUT-vWFcas2 was made blunt by filling in of 5' overhangs using Pwo DNA polymerase. Ligation of this fragment into EcoRI - AccI digested and Pwo treated pBluescript SKII, produced mutagenesis plasmid pBSvWF-NC. This plasmid retains the NheI and Csp45I restriction sites. Point mutations R963A, E987A, H990A, R1016A and H1023A were introduced in pBSvWF-NC. Mutation H1023A causes the disappearance of a NsiI restriction site. The NheI - Csp45I fragment of this mutant was ligated directly into pNUT-vWFcas2 and confirmed by restriction analysis. The NheI – Csp45I fragment of the other point mutants were ligated into pNUT-vWFcas2-H1023A, with reappearance of the NsiI site.

Expression, Purification and Characterization of vWF

vWF was stably expressed in fur-BHK cells, a baby hamster kidney cell line overexpressing furin necessary for proper removal of vWF propeptide^{6; 34}. VWF was purified by immuno-affinity chromatography using monoclonal antibody RU8, which is directed against the D4 domain⁶. VWF-containing fractions were pooled and stored in aliquots at –20 °C until use.

The concentration of vWF was determined by a sandwich ELISA using polyclonal α -vWF and horseradish peroxidase (HRP) conjugated polyclonal α -vWF (DAKO, Glostrup, Denmark) for immobilization and detection, respectively⁶. Normal pooled plasma from 40 healthy donors was used as a reference.

The multimeric structure of vWF was analyzed by agarose gel electrophoresis followed by Western blotting as described by Lawrie *et al.*³⁵.

Binding of vWF to monoclonal antibody RU5 was analyzed as follows. Microtiter-plate wells (Costar, Cambridge MA, USA) were coated with 2.5 μ g/ml polyclonal α -D'D3⁸ in 50 mM carbonate buffer pH 9.6 (3 h, 20 °C). Wells were washed with PBS/0.1% Tween-20 (PBS/T) and blocked with 3 % BSA in PBS/T (1 h, 37 °C). Wells were incubated with 100 ng/ml vWF in PBS/T including 3% BSA (1 h, 37 °C). After washing, 5 μ g/ml RU5 was added (1 h, 37 °C). Wells were washed and incubated with HRP conjugated swine-anti-rabbit antibody (DAKO, Glostrup, Denmark) diluted 1:2500 in PBS/T containing 3% BSA (1 h, 37 °C). O-phenylenediamine was used as substrate for detection.

Collagen-Binding Assay

vWF binding to fibrillar human placenta collagen type I (Sigma, St. Louis MO, USA, cat. No. C-7774) and collagen type III (Sigma, cat. No. C-4407) was studied in a solid-state binding assay according to Van der Plas *et al.*⁸. Collagen was coated at 50 µg/ml instead of 100 µg/ml as used previously⁸. A vWF concentration of 2.5 µg/ml was used in the binding experiments.

Results

A3-RU5 Structure Determination and Refinement

The structure of the vWF (Se-Met) A3-domain in complex with a Fab-fragment of RU5 was solved to 2.0 Å resolution. The structure was determined using the anomalous signal from selenium atoms in (Se-Met) A3 to position two A3 molecules and was completed by molecular replacement. The a.u. contains three A3-Fab complexes. The structure has been refined to an R-factor of 22.7% and a free R-factor of 26.4% (Table I).

The sequence of the RU5 V_L domain could not be determined from cDNA and was therefore deduced from electron density aided by an alignment of 110 Fab V_L sequences. The identity of thirteen amino acid residues could not be determined uniquely (see Fig. 1). The structure displays good model geometry with 88.8% of the residues in the most favored region of the Ramachandran plot and 10.8% in the additionally allowed region. Residue Thr51 of RU5 V_L domains occurs in the disallowed region of the Ramachandran plot, but its electron density is convincing.

The a.u. consists of three A3-RU5 complexes that are denoted *A*, *B* and *C*. The overall structure of the (Se-Met) A3 molecule is the same as the structure of native A3^{15;16}. It consists of a central six-stranded β-sheet on both sides flanked by α-helices. The final model comprises amino-acid residues 921-1110 of A3 molecules in complexes *A* and *B* and residues 920-1110 of the A3 molecule in complex *C*. Positions of the N- and C-termini of A3, including disulfide bond Cys923-Cys1109 that connects these termini, are poorly defined. The model of RU5 consists of residues 1-211 of the light chains and residues 1-129 and 136-216 of the heavy chains. Residues 130-135 of the heavy chains display very weak electron density and are excluded from the model. Disorder of this loop is a commonly observed feature in Fab structures³⁶. Asn56 of the V_H domain is N-glycosylated. Electron density near Asn56 accounted for a GlcNAc(-Fuc)-GlcNAc

moiety in complexes *A* and *B* and only a GlcNAc-Fuc moiety in complex *C*. The model contains one cacodylate ion from the crystallization solution.

Crystal Packing and Differences between Complexes

In the a.u. A3-RU5 complexes *B* and *C* form a tightly interacting anti-parallel dimer and are related by two-fold n.c.s. A3-RU5 complex *A* forms a similar anti-parallel dimer with a crystallographically related complex *A'*. Complexes within dimers *B-C* and *A-A'* have large contact areas of 932 Å² and 1,454 Å², respectively (GRASP³⁷). These large interaction-surface areas suggest that the dimer of A3-RU5 complexes may also be stable in solution. DLS measurements, however, clearly indicated that the A3-RU5 complex does not form dimers in solution. Therefore, dimers observed in the crystal are a result of crystal packing.

Superposition of C_α-atoms of the three A3-RU5 complexes gives large root-mean-square (r.m.s.) coordinate differences ranging from 0.7 to 0.9 Å. When superpositions are limited to A3 molecules with bound V_H and V_L domains r.m.s. coordinate differences of 0.5-0.6 Å are obtained. Visual inspection of these superpositions (figure 2) shows that the A3-RU5 interaction region is well conserved, whereas regions of A3 and the variable domains located further away from the interaction region superimpose less well. A more detailed inspection of the A3-RU5 binding region reveals that all side-chain conformations are very similar (data not shown). In conclusion, the A3-RU5 interaction region is well conserved among the three complexes in the a.u.

Figure 2: Structural overlay of C_α-traces of the three A3-RU5 Fab complexes in the asymmetric unit. For calculation of the best superposition C_α-atoms of A3 and variable domains of RU5-Fab were used. The A3-RU5 interaction region is well conserved amongst the three complexes, while relatively large differences are shown in orientations of the RU5 constant domains with respect to its variable domains and A3. The diagram was generated with MOLSCRIPT³⁸.

The Epitope of RU5

A3 interacts with RU5 through a non-linear epitope comprising residues in loop α1β2, loop β3α2 followed by helix α2, and loop α3β4 (Table II). All three loops that contribute to the epitope are

located in the bottom face of A3 (figure 3). The N- and C-termini of A3 that are also located in the bottom face do not interact with RU5. This observation is in agreement with the fact that RU5 was raised against complete vWF in which the termini connect A3 to flanking A2 and D4 domains. Residues of RU5 that interact with loops $\alpha 1\beta 2$ and $\alpha 3\beta 4$ are located in CDR_{L1} and CDR_{L2} (figure 1). All six CDRs interact with residues in the contiguous segment formed by loop $\beta 3\alpha 2$ and helix $\alpha 2$. The A3-RU5 interactions involve five hydrogen bonds and one salt bridge. The buried surface area of A3 molecules in the complex is approximately 1,200 Å², which is about 7% of the total surface area of A3. Interestingly, the fucose moiety attached to residue Asn56 in CDR_{H2} of complex *A* interacts with Lys988-Ala989 of A3. The carbohydrate moieties attached to Asn56 in complexes *B* and *C* do not interact with A3.

Conformational Changes in A3

To analyze whether binding of RU5 causes conformational changes in A3 we compared models of A3 in the A3-RU5 complex with two structures of free A3^{4 15; 16}. The two structures of free A3 were determined from different crystal forms with unrelated crystal-packing interactions. In both crystal forms two molecules are present in the a.u. Since the A3-RU5 complex was obtained with (Se-Met) A3 we also included the structure of free (Se-Met) A3 in the comparison to detect possible structural differences caused by Se-Met (E.G. Huizinga, unpublished results). R.m.s. coordinate differences after pair-wise superimposing C α -atoms of all eight models range from 0.24 to 0.81 Å. Large differences are restricted to three loops located within the RU5-binding site and to two loops that are located distant from the epitope (figure 3, Table II).

The three conformational diverse loops located in the RU5-epitope are $\alpha 1\beta 2$, $\beta 3\alpha 2$ and $\alpha 3\beta 4$ (figure 4A). Loop $\alpha 1\beta 2$ has a unique conformation in the A3-RU5 complex, indicating that this conformation is induced by RU5. Loops $\beta 3\alpha 2$ and $\alpha 3\beta 4$ have considerable conformational freedom. Conformations observed in the A3-RU5 complex are, however, not systematically different from the conformations observed in free A3, indicating that the conformations observed in the complex are not induced by RU5.

Distant from the RU5 epitope conformational variation is observed for loops $\beta 1\alpha 1$ and $\alpha 5\beta 6$. Loop $\beta 1\alpha 1$ is located in the top face of the domain and contains part of the vestigial MIDAS motif. Multiple conformations are observed for residues Ser938-Phe-Pro940 (figure 4B). Phe939 is solvent exposed in A3-RU5 complex *C* and all models of free A3. In complexes *A* and *B* Phe939 is buried in the hydrophobic core of A3. The buried conformation is likely caused by

crystal packing interactions involving A3 residues 940-942. These packing interactions would not allow for the position of Pro940 observed in models of A3 that have an exposed conformation of Phe939. Since both the exposed and buried conformations of Phe939 are observed in the three A3-RU5 complexes the conformation of this loop is certainly not determined by binding of RU5.

Figure 3: Ribbon diagram of A3 and RU5 variable domains. Residues of A3 that are part of the epitope of RU5 are indicated by yellow spheres. Regions of RU5 CDRs that interact with A3 are color-coded in light blue. Regions of A3 that show different conformations among four crystal structures are shown in purple trace. Disulfide bond Cys923-Cys1109 is shown in green ball-and-stick. The α -helices and β -strands of A3 are depicted in blue and red, respectively. For clarity, α -helix 2 is not shown by a ribbon, but in 'coil' representation. The V_H domain of RU5 is in brown, the V_L domain is in green. The diagram was generated with MOLSCRIPT³⁸ and RASTER3D³⁹.

Loop $\alpha 3\beta 4$	Thr1019-Ser-Glu- <u>Met-His-Gly</u> -Ala1025
Loop $\alpha 5\beta 6$	Gly1078-Pro-Ala-Gly-Asp-Ser1083

^a Residues listed are positioned within 4.0 Å distance from RU5.

^b Residues that are also part of the epitope of RU5 are underlined.

Loop $\alpha 5\beta 6$ located in a side face of A3 has an aberrant conformation in A3 domain *B* of the structure of Bienkowska *et al.*¹⁶ (figure 4C). This aberrant conformation coincides with crystal contacts unique to molecule *B*. No crystal contacts are present in the other structures. The conformations observed in the A3-RU5 complex are not systematically different from the conformations observed in free A3. Thus, binding of RU5 does not cause conformational changes in regions of A3 that are distant from the epitope.

Figure 4: The conformation of five loops varies among different crystal structures of A3. Models compared include free A3⁴, free (Se-Met) A3 and A3 from the A3-RU5 complex. *A.* Stereo picture of loops $\alpha 1\beta 2$ (residues 961-963), $\beta 3\alpha 2$ (983-987) and $\alpha 3\beta 4$ (1019-1025). Residues of A3 in A3-RU5 complex *A* are shown in thick line. A3 domain *A* from the structure of Huizinga *et al.*¹⁵ is shown in gray. *B.* Stereo diagram of residues Ser938-Phe-Pro940 in the top face of A3. Buried and exposed conformations of Phe939 are labeled. *C.* Stereo diagram of loop $\alpha 5\beta 6$ (residues 1078-1083). The aberrant A3 domain *B* from the structure of Bienkowska *et al.*¹⁶ is shown in thick line. The diagram was generated with MOLSCRIPT³⁸.

Selection and Characterization of vWF Mutants

To confirm the location of the collagen-binding site indicated by the A3-RU5 complex we constructed charged-to-alanine mutations of five residues. These residues are located within 5 Å of the RU5 Fab fragment and are solvent exposed in free A3. Residues selected were Arg963 located in loop $\alpha 1\beta 2$, Glu987 ($\beta 3\alpha 2$), His990 ($\alpha 2$), Arg1016 ($\alpha 3$), and His1023 ($\alpha 3\beta 4$). Mutants were produced as multimeric vWF in stable baby hamster kidney cell lines. The multimer distribution of vWF mutants and wild-type vWF, as analyzed by agarose gel electrophoresis, were

indistinguishable (data not shown). RU5 binding to purified point mutants was not significantly different from RU5 binding to wild-type vWF (figure 5).

Figure 5: Binding of monoclonal antibody RU5 to vWF mutants. VWF immobilized in microtiter-plate wells via polyclonal α D'D3 was incubated with 5 μ g/ml RU5. Bound RU5 was detected by horse radish peroxidase conjugated swine-anti-rabbit antibody as described under "Experimental Procedures". Wild-type vWF and Δ A3-vWF, which lacks the A3 domain ⁶, were used as positive and negative controls, respectively. Binding of RU5 to vWF mutants was percentualized against wt-vWF. Each data point represents the mean \pm SD of two measurements in duplicate.

Collagen Binding of vWF Mutants

The effect of point mutations on vWF binding to collagen types I and III was investigated by ELISA (figure 6). Similar results were obtained for both types of collagen. Mutation H1023A almost completely abolished collagen binding. The level of residual binding observed for this mutant was similar to binding observed for Δ A3-vWF, a deletion mutant that lacks the entire A3 domain ⁶. Collagen binding of mutants R963A and R1016A was reduced by 25 - 35%, whereas collagen binding of mutants E987A and H990A was normal.

Figure 6: Binding of vWF point mutants to collagen types I and III. Collagen type I (white bar) or III (black bar) was coated in microtiter-plate wells. Wells were incubated with vWF at a concentration of 2.5 μ g/ml and bound vWF was detected as described under "Experimental Procedures". Δ A3-vWF was used as a negative control. Bound vWF mutant was percentualized against wt-vWF. Each data point represents the mean \pm SD of three independent experiments performed in duplicate.

Discussion

The current study was aimed at locating the collagen-binding site of the vWF-A3 domain. For this purpose we solved the crystal structure of A3 in complex with a Fab fragment of RU5 that inhibits collagen binding. The structure of the complex shows that RU5 binds to residues within A3 sequences 962-966, 981-997 and 1022-1026. These residues are located in α -helix 2 and in loops $\alpha 1\beta 2$, $\beta 3\alpha 2$ and $\alpha 3\beta 4$ at the bottom of one of the side faces of the A3 domain (see figure 3). Comparison of structures of A3 shows that RU5 binding does not induce long range conformational changes. This excludes a mechanism in which RU5 induced conformational changes inhibit collagen binding. It seems likely, therefore, that RU5 inhibits collagen binding by steric hindrance, which implies that the collagen-binding site is located at or close to the RU5 epitope.

To confirm the location of the collagen-binding site we constructed five charged-to-alanine mutations of residues located in or close to the RU5 epitope. The multimer distribution of these mutants was similar to that of wild-type vWF. Therefore, observed differences in collagen binding are not caused by the known dependence of collagen binding on vWF multimer-size⁷. All five mutants bound normally to RU5, which shows that none of the mutated residues plays a dominant role in the A3-RU5 interaction and, more importantly, that the conformation of A3 in the neighbourhood of the epitope and the collagen-binding site is not disturbed.

Mutation H1023A abolished collagen binding almost completely, residual-binding being similar to that observed for Δ A3-vWF, a deletion mutant that lacks the entire A3 domain. Therefore, His1023 plays a central role in A3-mediated collagen binding. His1023 is located in loop $\alpha 3\beta 4$ and lies at the edge between the 'front' face of the domain, formed by helices $\alpha 2$ and $\alpha 3$ and strand $\beta 3$, and the bottom face, which is composed of several loops and contains the N- and C-termini (see figure 7). A small reduction of collagen binding was observed for mutants R963A and R1016A located in the bottom and front face of the domain, respectively.

Figure 7: Residues of vWF-A3 involved in collagen binding. Stereographic representation of the vWF-A3 domain showing amino-acid residues that have been mutated to alanine in ball-and-stick. Mutation of His1023 (magenta) abolishes collagen binding almost completely. Mutation of Arg963 and Arg1016 (green) reduces collagen binding by 25-35%. Mutation of Glu987 and His990 (gray) does not have an effect on collagen binding. To illustrate the range of conformations of His1023 observed in different crystal forms of A3, two conformations of this residue and the backbone trace of flanking residues are shown. Residues that have been mutated in previous studies^{8; 16; 19} are located in the top face of A3 and are indicated by black spheres. The diagram was generated with MOLSCRIPT³⁸ and RASTER3D³⁹.

Interestingly, His1023 and flanking residues display a large variety of conformations among eight models of A3 (figures 4 and 7). In some A3 structures His1023 protrudes prominently from the surface of the domain which may be a favorable position for interaction with collagen. Multiple conformations are also observed for loop $\beta 3\alpha 2$. Like His1023, loop $\beta 3\alpha 2$ is located at the edge between the front and bottom faces of A3. Since we did not mutate residues in loop $\beta 3\alpha 2$ its involvement in collagen binding remains to be established. The observed flexibility of His1023 suggests that collagen binding may involve an induced-fit mechanism in which significant conformational changes occur in loop $\alpha 3\beta 4$ upon binding of A3 to collagen.

The amino-acid sequence of collagen that is recognized by vWF-A3 has not yet been identified. We hypothesized previously that negatively charged residues in A3 could interact with basic residues on collagen¹⁵. Residues now implicated in collagen binding are positively charged. Therefore, interaction of A3 with negatively charged residues on collagen appears more likely.

In contrast to binding sites of other collagen binding domains, like the α_1 , α_2 I-domains and the A-domain of *S. aureus* adhesin^{12; 40}, the collagen-binding region of A3 does not have a groove or trench that could accommodate a collagen triple-helix. The front face of the domain, harboring Arg1016, is rather flat. The bottom face, which contains Arg963 is less smooth, but no groove is present. Docking of a collagen triple-helix on the A3 domain is not straightforward. In particular, it is not obvious how His1023, Arg963 and Arg1016 could simultaneously contact a

triple-helix in an extended conformation. To define the collagen-binding site more precisely, characterization of additional mutants will be necessary.

Previously, the collagen-binding site of A3 was proposed to be located at its top face^{15; 19} similar to the homologous I-domains of integrins $\alpha_1\beta_1$ and $\alpha_2\beta_1$ ^{12; 41-43}. Point mutations introduced in the top face of an A3 monomer¹⁹ and in multimeric vWF⁸ gave conflicting results. Our results now show conclusively that the collagen-binding site is located close to the bottom face and not in the top face of A3.

While our results rule out a role for the top face of the A3 domain in collagen binding, this side of the molecule may still be engaged in other interactions, such as binding of the A1 domain. Interaction between A1 and A3 has been suggested to play a role in activation of the A1 domain for binding to platelet receptor glycoprotein Ib⁴⁴. Interesting in this respect are the buried and solvent exposed conformation observed for residue Phe939, which is located close to the vestigial MIDAS motif in the top face of the domain (figure 4B). Solvent exposure of Phe939 has been proposed to stabilize the buried Asp934 of the vestigial MIDAS motif in the absence of a bound metal ion¹⁶. Our observation of a buried conformation shows that exposure of Phe939 is not critical for structural stability. The two conformations of Phe939 may, however, be relevant for the putative interaction between A1 and A3, since the shape and hydrophobicity of the upper surface of A3 differs significantly between the solvent exposed and buried conformation.

In conclusion, the collagen-binding site of vWF-A3 is distinctly different from collagen-binding sites of I-domains of integrins $\alpha_1\beta_1$ and $\alpha_2\beta_1$. VWF-A3 residues involved in collagen binding are located close to the bottom face of the domain. His1023 is essential for collagen binding, while Arg963 and Arg1016 play ancillary roles. Multiple conformations observed for His1023 and adjacent residues suggest that binding of A3 to collagen involves an induced-fit mechanism.

Summary

Von Willebrand factor (vWF) is a multimeric plasma glycoprotein that mediates platelet adhesion to collagen at sites of vascular damage. VWF binds to collagen via its A3 domain. Recently we identified the approximate location of the collagen-binding site in the vWF-A3 domain ([JBC, 276, 2001, 9985-9991](#)). In this paper we have studied 22 point mutants to map the collagen-binding site in detail. Our results map the collagen-binding site at strand $\beta 3$, helix $\alpha 3$ and loops $\beta 2\beta 3$, $\alpha 2\alpha 3$ and $\alpha 3\beta 4$ at the “front” face of the domain. Residues Asp⁹⁷⁹, Ser¹⁰²⁰ and His¹⁰²³ in the lower half of the collagen-binding site are essential for collagen binding, whereas Ile⁹⁷⁵, Thr⁹⁷⁷, Val⁹⁹⁷, Glu¹⁰⁰¹ and Arg¹⁰¹⁶ in the upper part play an additional role. These residues define a rather flat collagen-binding site. Most likely, multiple collagen sequences bind to A3. Surface properties of the collagen-binding site indicate that collagen sequences containing hydrophobic and positively charged residues binds to A3.

Introduction

Human vessel wall has a high content of collagen sub-types I, III, IV, V, VI, VIII, XII, XIII and XIV¹⁻³ that determine the thrombogenicity of the vessel wall. Blood is separated from these components by a thin layer of endothelial cells. Upon disruption of the endothelial cell layer blood is exposed to collagens in the vessel wall.

Collagen subtypes I, III, IV and VI are strong activators of platelet adhesion and aggregation (see for reviews³⁻⁶). At low shear force platelets interact directly with collagen via integrin $\alpha_2\beta_1$ and glycoprotein (Gp) VI⁵. At high shear force platelet adhesion to collagen is a von Willebrand factor (vWF) dependent process^{6, 7}. In this process, vWF functions as a molecular bridge between collagen and platelet receptor GpIb-IX-V complex. Human fibrillar collagen type I and III from perivascular connective tissue are the main collagen subtypes that interact with the vWF-A3 domain^{8, 9}. Collagen type VI from subendothelial cell matrix also interacts with vWF, but the binding site for collagen type VI appears to be located in the A1 domain^{10, 11}.

Mature monomeric vWF contains 2050 amino-acid residues and is composed of twelve domains in the order D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK^{6, 12}. VWF dimerises at the CK domains¹³ and multimerises at the D3 domains¹⁴. VWF with a reduced multimeric size has a decreased affinity for collagen¹⁵.

VWF-mediated platelet adhesion to collagen subtypes I and III involves first the binding of the A3 domain to collagen and subsequently the binding of the A1 domain to platelet receptor GpIb α *in vitro*¹⁶⁻¹⁸. Recently, Wu *et al.* showed for the first time in an *in vivo* model that the vWF-A1 and A3 domains are essential in thrombus formation^{19, 20}. A-type domains and homologous integrin I-domains adopt a so-called di-nucleotide-binding fold, or Rossman fold composed of a central β -sheet surrounded by six or seven α -helices²¹⁻²⁴. Binding of the I-domain of integrins α_1 , α_2 , α_{10} and α_{11} to collagen involves a divalent cation^{25, 26} bound to the metal ion dependent adhesion site (MIDAS) motif and amino-acid residues at the “top” face of the domain^{27, 28}. The A3 domain does not contain a functional MIDAS motif and binding of A3 to collagen is cation independent^{29, 30}. Recently we have identified His¹⁰²³, Arg⁹⁶³ and Arg¹⁰¹⁶ located at the front- and bottom face of A3 to be involved in collagen binding³¹. Mutation H1023A completely

abolished collagen binding, whereas mutations R963A and R1016A reduced collagen binding by 20 – 30 %.

This study was aimed at identifying the collagen-binding site in the vWF-A3 domain in detail by means of site-directed mutagenesis. We did so by constructing nineteen alanine mutants and three histidine mutants that were expressed as multimeric vWF. Collagen-binding was evaluated.

Experimental procedures

Selection and construction of vWF Point Mutants

Selection of amino-acid residues for mutagenesis was based on the approximate location of the collagen binding site as identified in our previous study³¹ and the crystal structure of the vWF-A3 domain^{21; 22}. Selected residues are solvent exposed in the isolated A3 domain. Residues Gln⁹⁶⁶, Ser⁹⁷⁴, Ile⁹⁷⁵, Thr⁹⁷⁷, Asp⁹⁷⁹, Val⁹⁸⁰, Pro⁹⁸¹, Asn⁹⁸³, Val⁹⁸⁴, Val⁹⁸⁵, Ser⁹⁹³, Val⁹⁹⁷, Gln⁹⁹⁹, Glu¹⁰⁰¹, Gln¹⁰⁰⁶, Asp¹⁰⁰⁹, Ser¹⁰²⁰, Glu¹⁰²¹ and Met¹⁰²² were mutated to alanine. In addition, Pro⁹⁶², Pro⁹⁸¹ and Pro¹⁰²⁷ were mutated to histidine to inhibit collagen binding by steric hindrance. Backbone conformations of these proline residues suggested that the histidine side chain would protrude from the protein surface.

Point mutations were introduced in the vWF-A3 domain using the Quikchange method (Stratagene, La Jolla CA, USA) as described previously³¹.

Expression, Purification and Characterization of vWF

VWF was stably expressed in baby hamster kidney cells overexpressing furin required for proper removal of vWF propeptide^{17; 32}. Cells were cultured in serum-free medium. VWF was purified by immuno-affinity chromatography using monoclonal antibody RU8, which is directed against the D4 domain¹⁷ and stored in 50 mM Hepes, 100 mM NaCl pH 7.4 at –20 °C.

VWF concentration was determined by a sandwich ELISA using polyclonal α -vWF and horseradish peroxidase (HRP) conjugated polyclonal α -vWF (DAKO, Glostrup, Denmark) for immobilization and detection, respectively¹⁷. Normal pooled plasma from 40 healthy donors was used as a reference.

The multimeric structure of vWF was analyzed by agarose gel electrophoresis followed by Western blotting as described by Lawrie *et al.* ³³.

Binding of monoclonal antibody RU5 ³⁴ to vWF was analysed as described before ³¹ with some modifications. Microtiter-plate wells (Costar, Cambridge MA, USA) were coated with a polyclonal antibody directed against the D' and D3 domains of vWF ³⁴ diluted to 2.5 µg/ml with 50 mM carbonate buffer pH 9.6. Coating was carried out for 3 h at 37 °C. Wells were washed with PBS containing 0.1% Tween-20 (PBS-T) and blocked with 3 % BSA in PBS-T for 1 h at 37 °C. Expression medium containing (mutant) vWF was diluted with mock medium to a final concentration of 1 µg/ml vWF. Wells were incubated with diluted medium for 1 h at 37 °C. After washing, 2 µg/ml RU5 in PBS-T containing 3% BSA was added for 1 h at 37 °C. Wells were washed again and incubated for 1 h at 37 °C with HRP-conjugated rabbit-anti-mouse antibodies (DAKO, Glostrup, Denmark) diluted 1:2500 in PBS-T containing 3% BSA. O-phenylenediamine was used as substrate for detection.

Static Collagen-Binding Assay

Binding of vWF in expression medium to fibrillar human placenta collagen type III (Sigma Chemical Co., St. Louis MO, USA, cat. No. C-4407) was studied in a solid-state binding assay at a vWF concentration of 0.1 µg/ml as described before ³¹.

Surface Plasmon Resonance Collagen-binding Assay

Surface Plasmon Resonance (SPR) binding studies were performed using a Biacore2000 system (Biacore AB, Uppsala, Sweden). Human placenta collagen type III was dissolved in 50 mM acetic acid at a final concentration of 1 mg/ml (16h, 4 °C) and immobilized on a CM5-biosensor chip using the amine-coupling kit as instructed by the supplier. Approximately 3000 RU, corresponding with ~33 fmol/mm², collagen type III was immobilized. A reference channel was coated with human placenta collagen type IV (3000 RU; Sigma, cat. No. C-7521) that does not interact with vWF ⁵. Analysis was performed in Biacore standard buffer 25 mM Hepes, 125 mM NaCl, 2.5 mM CaCl₂, 0.005% (v/v) Tween-20, pH 7.4 at 25 °C at a flow rate of 10 µl/min. Binding of vWF to the collagen type III-coated channel was corrected for binding to the collagen type IV-coated channel. Binding isotherms were determined by injecting increasing concentrations of vWF. Each injection was continued for 30 minutes, facilitating accurate

determination of the steady state (R_{eq}) by fitting the binding curve with a 1:1 Langmuir interaction model (Biaevaluation software version 3.0.1), which gave the best fit with the experimental data. The delay between two subsequent injections was seven minutes in which the biosensor chip was flushed with biacore-standard buffer without regeneration. After measuring all concentrations of a vWF-variant, the biosensor chip was regenerated by injection of 1 mM EDTA, 1 M NaCl, 0.1 M sodium citrate, pH 5.0 (1 min, 10 μ l/min) and 10 mM taurodeoxycholic acid, 100 mM Tris, pH 9.0 (1 min, 10 μ l/min) and 0.1 M H_3PO_4 (1 min, 10 μ l/min).

Binding isotherms were constructed using the computer program GraphPad Prism 3.0³⁵. The response units at equilibrium (R_{eq}) were plotted against the injected vWF concentration and the data points were fitted with a 1:1 interaction model $R_{eq} = R_{eq,max} * [vWF] / (K_D + [vWF])$, where $R_{eq,max}$ is the response at infinite vWF concentration and K_D is the dissociation constant. Since the interactions between vWF and collagen are multivalent and we used a 1:1 interaction model, the calculated dissociation constants must be regarded as apparent values.

Results

Characterization of vWF Mutants

The conformation of the A3 domain and the multimeric size of vWF determine its reactivity towards collagen. Multimer distributions of vWF mutants and recombinant wt-vWF were indistinguishable (data not shown). The conformation of the A3 domain was evaluated with conformation dependent monoclonal antibody RU5. Binding of RU5 to 18 of the 22 point mutants was similar as the binding of RU5 to wt-vWF. As expected, RU5 did not bind to vWF lacking the A3 domain, $\Delta A3$ -vWF¹⁷ (figure 1A). Four of the point mutants, P962H, P981A, V984A and V985A, had a significantly reduced RU5 binding, ranging from 60 to 80 % compared to wt-vWF. However, collagen binding of these mutants was normal (see below). Reduced RU5-binding can be explained by direct interactions of these residues with RU5, as observed in the crystal structure of the A3•RU5 complex³¹. Overall, these data suggest that the A3 domain of all vWF-variants is correctly folded.

Figure 1: Characterisation of vWF-A3 mutants. A: Binding of conformation dependent monoclonal antibody RU5. VWF was immobilized in microtiter-plate wells via polyclonal antibody α D'D3. Immobilized vWF was incubated with RU5 and bound RU5 was detected as described under "Experimental Procedures". Wild-type vWF and Δ A3-vWF, which lacks the A3 domain¹⁷, were used as a positive and negative control, respectively. Binding of RU5 to vWF mutants is expressed as a percentage of wt-vWF binding. Each data-point represents the mean \pm SD of three experiments performed in duplicate. B: Binding of vWF point mutants to fibrillar collagen type III in a solid-state collagen-binding assay. Human placenta collagen type III was coated in microtiter-plate wells. Wells were incubated with vWF at a concentration of 0.1 μ g/ml. Bound vWF was detected as described under "Experimental Procedures". Δ A3-vWF¹⁷ was used as a negative control. Bound vWF is expressed as a percentage of wt-vWF binding. Each data point represents the mean \pm SD of three independent experiments performed in duplicate.

Collagen Binding Affinity of vWF Mutants

In a first screen the effect of the mutations in collagen type III binding was assessed by a solid-state collagen-binding assay (figure 1B). Immobilized collagen was incubated with expression medium at a vWF concentration of 0.1 $\mu\text{g/ml}$. Binding of $\Delta\text{A3-vWF}$ to collagen was only 8 % compared to wt-vWF. Mutations I975A, T977A, D979A, P981H, V997A, E1001A and S1020A strongly reduced collagen binding, showing a residual binding of less than 25 %. To further investigate the effect of the seven mutations, these mutants, and mutant H1023A from our previous study³¹, were purified by immuno-affinity chromatography. Collagen binding of the purified mutants was analysed by surface plasmon resonance (SPR). In addition to wt-vWF, mutants P981A and E1021A that bound normally to collagen in the solid-state collagen-binding assay were selected as positive controls.

Binding isotherms of purified vWF-variants were determined. Human placenta collagen type III was coated at a density of 3000 RU. Wild-type vWF bound dose dependent and saturable to collagen type III, with an apparent K_D of 3.6 ± 0.4 nM and a maximum binding at equilibrium, $R_{eq,max}$, of 521 ± 14 RU (figure 2, Table I).

Figure 2: Binding-isotherms of vWF mutants to collagen type III in an SPR-based assay. Human placenta collagen types III and IV were immobilized on a CM5 biosensor chip for a detection and reference channel, respectively. Wild-type vWF and wt-vWF pre-incubated with a five-fold molar excess of RU5 Fab-fragment were used as a positive and negative control, respectively. Sequentially, increasing concentrations of vWF variants were injected and equilibrium binding was determined.

Table I

Dissociation- and maximum binding at equilibrium
for the vWF – collagen interaction

vWF variant	K_D^1 (\pm SD) (nM)	$R_{eq,max}^1$ (\pm SD) (RU)
wt-vWF	3.6 (0.4)	521 (14)
P981A	2.9 (0.0059)	440 (0.14)
E1021A	6.3 (0.69)	540 (14)
I975A	19 (3.0)	352 (20)
T977A	27 (4.7)	419 (38)
V997A	26 (2.7)	551 (23)
E1001A	42 (8.8)	310 (31)
D979A ²		50
P981H	1.8 (0.26)	120 (3.4)
S1020A ²		30
H1023A ²		50

¹ Since vWF and collagen are multivalent and we used a 1:1 interaction model to fit the experimental data these values must be regarded as apparent.

² Collagen-binding of these variants was too low to calculate reliable dissociation constants.

Addition of the RU5 Fab fragment to wt-vWF almost completely inhibited collagen binding, confirming that the A3 domain contains the binding site for collagen type III. Mutants P981A and E1021A that bound normally to collagen in the solid-state collagen-binding assay also had similar binding affinities and number of binding sites as wt-vWF for collagen in the SPR-based assay. Mutants that exhibited strongly reduced collagen-binding in the solid-state assay divided in two populations in the SPR collagen-binding assay. Mutations I975A, T977A, V997A and E1001A reduced the affinity of vWF for collagen five to ten fold, whereas at saturation the number of binding sites was at least 60 % compared to wt-vWF (Table I). Mutants D979A, P981H, S1020A and H1023A had a residual binding at saturation of less than 20 % compared to wt-vWF. The affinity could be calculated only for mutant P981H and it was similar to wt-vWF.

As shown in figure 3A, mutations that reduce collagen binding are located at the front face of the domain and define a rather flat collagen-binding site. Mutations at the bottom face did not have an effect. Interestingly, mutations that strongly inhibit collagen binding cluster at the lower part of the collagen-binding site, whereas mutations that partially inhibit collagen binding cluster at the upper part.

Figure 3: Characteristics of the collagen-binding site on the vWF-A3 domain. The front-face of the A3 domain is shown. A: Representation of the A3 domain that shows the effect of mutations in collagen-binding by colour. Residues in *magenta* display strongly reduced collagen binding. Residues in *green* display a partially reduced collagen binding, whereas collagen binding of residues in *grey* is comparable to recombinant wt-vWF. Pro⁹⁸¹ is shown in *red*. The effect of five mutations investigated in our previous study ³¹, R963A, E987A, H990A, R1016A and H1023A, are included in the figure.

B: Solvent accessible surface with electrostatic potential contoured from *red* (-10kT/e) to blue (+1- kT/e). C: Solvent accessible surface with hydrophobic- and hydrophilic regions in *green* and *white*, respectively. D: CPK-representation of the A3 domain with two collagen triple helices that indicate the putative range of orientations for the A3-collagen interaction. Residues of A3 are color-coded as in figure 3A, except that residues that show no effect in collagen binding are colored in *yellow* and residues of which no data are available are shown in *grey*.

Surface properties of the collagen binding site are shown in figures 3B and 3C. The upper part of the collagen binding site contains a small negatively charged patch. In addition, the collagen binding site contains one large and two smaller hydrophobic patches.

Docking of a Collagen Triple Helix on A3

Identification of residues involved in collagen binding allows us to dock a collagen triple helix on A3. Attempts using an automated procedure³⁶ were not successful. Possibly this was caused by the use of a triple helix consisting of glycine-proline-hydroxyproline repeats, because specific collagen sequences that interact with A3 have not been identified. Therefore, we manually docked a collagen triple helix on A3 using the computer program O³⁷ and the following constraints: (i) the diameter of a collagen triple helix is approximately 17 Å, (ii) all residues shown to be involved in collagen binding should contact the triple helix, and (iii) since RU5 blocks collagen binding to A3, the position of the triple helix should overlap the position of the RU5 Fab fragment³¹. A broad range of orientations of a collagen triple helix on A3 fulfil these constraints (figure 3D). Six to eight consecutive collagen residues interact with the A3 domain.

Discussion

Von Willebrand Factor A-type domains are found in many proteins including collagens, complement proteins and integrins where they are named I-domains. These proteins are involved in several biological functions like cell-cell interaction and ligand-receptor binding. In integrins, these interactions are mediated by a divalent cation present in the MIDAS motif at the top of the domain.

vWF contains three A-type domains, of which the A3 domain binds to collagen. The vWF-A3 domain does not contain a functional MIDAS motif and collagen binding is cation independent^{21; 29}. Previously, we have identified the approximate location of the collagen binding site³¹. Based on these results we constructed a panel of twenty-two point mutants in which solvent exposed residues were mutated to either alanine or histidine. These mutations were introduced into multimeric vWF, and collagen-binding was evaluated.

Collagen binding of the point mutants was screened in a solid-state collagen-binding assay. Seven of the twenty-two mutants, I975A, T977A, D979A, P981H, V997A, E1001A and S1020A, displayed reduced collagen binding. Because the solid-state collagen-binding assay is a static assay that reveals collagen-binding under non-equilibrium conditions, we further characterised these seven mutants and mutant H1023A, which also binds strongly reduced to collagen³¹, by SPR under equilibrium conditions. The apparent dissociation constant of wt-vWF for collagen was 3.6 nM, which is similar to values determined by van der Plas *et al.* and Saenko *et al.*^{34; 38}. Addition of a five-fold molar excess of the RU5 Fab fragment to wt-vWF completely abolished collagen binding. Interestingly, at equilibrium conditions the mutants that were qualified as “strongly reduced” in the solid-state assay now separated in two groups. Collagen binding of mutants D979A, S1020A and H1023A, was 80 – 90 % inhibited and therefore these residues are essential for collagen binding. Mutants I975A, T977A, V997A and E1001A, were characterised by a 5 – 10 fold reduced affinity, but had a normal number of binding sites suggesting that these residues are involved in collagen binding, but are not essential. Mutation P981H strongly reduced collagen binding but the apparent affinity is similar to wt-vWF. Interestingly, mutation P981A did not reduce collagen binding. This indicates that Pro⁹⁸¹ is spatially very close, but does not interact with the collagen triple helix. Most likely, mutation P981H inhibits via sterical hindrance the binding of collagen sequences that contain large residues, but does not affect the binding of other collagen sequences.

Mutated residues that displayed reduced collagen binding define the collagen-binding site at the front face of A3. Residues that are essential in collagen binding, residues Asp⁹⁷⁹, Ser¹⁰²⁰ and His¹⁰²³, cluster at the lower part of the collagen-binding site and are located in strand $\beta 3$ and loop $\alpha 3\beta 4$. Residues that bind to collagen, but are not essential, residues Ile⁹⁷⁵, Thr⁹⁷⁷, Val⁹⁹⁷, Glu¹⁰⁰¹ and Arg¹⁰¹⁶, cluster at the upper part of the collagen-binding site and are located in loops $\beta 2\beta 3$, $\alpha 2\alpha 3$, helix $\alpha 3$ and strand $\beta 3$. Previously we hypothesised the possible involvement of loop $\beta 3\alpha 2$ in collagen binding³¹, but mutations in this loop did not inhibit collagen binding excluding its involvement. None of the mutations at the bottom-face of A3 reduced collagen binding and therefore we excluded the A3 bottom face to be involved in collagen binding.

High affinity sites within collagen to which vWF binds are still unknown. Based on the surface characteristics of the collagen-binding site, we suggest that a collagen triple helix containing positively charged and hydrophobic residues binds A3. Since mutation P981H

strongly reduces the number of collagen binding sites with retaining normal affinity, whereas mutation P981A does not affect collagen-binding at all, it suggests that the collagen triple helix is spatially close to Pro⁹⁸¹ and may contain a large residue. In addition to this it is likely that A3 recognizes multiple collagen sequences. Also for the I-domain of α_1 integrin it has been observed that it recognizes multiple collagen sequences³⁹.

Manual docking of a collagen triple helix on the front face of the A3 domain suggested a broad range of engagements of a collagen triple helix on the A3 domain (figure 3D). Therefore the models must be regarded as a crude approximation. This model predicts that at most eight consecutive residues in a collagen molecule interacts with A3.

The vWF-A3 collagen-binding site is located at the front face of the domain, whereas the collagen-binding site of homologous integrin I-domains is located at the top and requires a functional MIDAS motif^{27; 40}. The collagen-binding site of I-domains contain a protruding helix that determines the specificity towards collagen^{24; 41}. The collagen-binding site of A3 does not contain such a protruding helix and it is rather flat. This suggests a low specificity of A3 for collagen sequences.

Recently, four mutations (S968T, Q971H, I978T, Q999R) in the A3 domain have been identified in patients that have either no or mild bleeding problems^{42; 43}. This questions the relevance of the A3 domain for immobilisation of vWF to the vascular matrix⁴². However, Wu *et al.*²⁰ characterised a monoclonal antibody that binds to A3 and inhibits platelet adhesion *in vivo*, confirming the relevance of the A3 domain in the vWF – collagen interaction. In addition, these four residues are located in the region of the collagen-binding site that contains residues that are involved but not essential in collagen binding. Such mutations may therefore not give bleeding symptoms. In contrast, mutations in the region that contains residues that are essential in collagen binding may be associated with bleeding symptoms.

In summary, we mapped the collagen-binding site at the front face of the domain. Residues in the lower half of the collagen-binding site are essential for collagen binding, whereas residues in the upper half are involved but not essential. We suggest that a collagen triple helix that interacts with A3 contains hydrophobic and positively charged residues. Further understanding of the vWF-collagen interaction requires the identification of specific collagen sequences involved in vWF binding.

Summary

vWF is a multimeric plasma glycoprotein that mediates platelet adhesion at sites of vascular damage. The collagen-binding site has been mapped to the front face of the vWF-A3 domain. Recently a patient has been reported with mutation Ser968Thr in the A3 domain that reduced collagen type I binding. In the present study we have evaluated binding of Ser968Thr-vWF to collagen type III. In addition platelet adhesion to collagen type III was evaluated in the presence of vWF containing this mutation. Whereas collagen binding of Ser968Thr-vWF was similar as the binding of wt-vWF to collagen, platelet adhesion in the presence of Ser968Thr-vWF was 40 % reduced.

We solved the crystal structure of Ser968Thr-A3. In the crystal structure we did not observe long- or short range conformational changes. However, since some loops at or close to the collagen binding site are flexible, we suggest that mutation Ser968Thr shifts the equilibrium between the conformations of these loops. This switches A3 from a high- to a low-affinity conformation and thereby reduces collagen binding.

Introduction

Von Willebrand factor (vWF¹) is a large multimeric plasma glycoprotein. At sites of vascular damage it serves as a molecular bridge between collagen and the glycoprotein Ib-IX-V complex on the platelet, thereby initiating thrombus formation (reviewed in ¹). A dysfunctional vWF may lead to bleeding complications.

Mature vWF contains 2050 amino-acid residues that are arranged in domains D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK. Dimer formation involves interchain disulfide bond formation between CK domains, whereas multimers are formed by interchain disulfide bonds between D3 domains. VWF multimers contain up to 80 monomers ². Multimerisation is important for the function of vWF, because smaller multimers have a reduced affinity toward collagen and are less active in platelet aggregation ³. The vWF-A3 domain is essential for platelet adhesion *in vivo* ⁴, since it contains the primary binding site collagen for collagen types I and III ⁵ that are constituents of the deeper layers of the vessel wall ⁶. The collagen-binding site in A3 is located at the front face of the domain ⁷. This is in contrast to homologous integrin I-domains, like the α_2 -I domain, which contains the collagen-binding site at the top face ⁸. Moreover, collagen binding by the vWF-A3 domain is cation independent ⁹, whereas integrin I-domains require the presence of a divalent cation in the metal ion dependent adhesion site motive ^{10; 11}.

Qualitative or quantitative defects in vWF cause von Willebrand disease (vWD) ¹², a very mild to severe bleeding disorder. Recently a new dysfunctional phenotype of vWF has been found with a reduced collagen binding activity, resulting in a mild bleeding tendency ¹³. This was caused by mutation Ser968Thr in the vWF-A3 domain. In A3, residue Ser⁹⁶⁸ is not solvent exposed but it is located under the surface of the collagen binding site ⁷. The mechanism by which this mutation reduces the affinity of A3 for collagen is not understood.

In this study, we investigated the platelet adhesive properties of recombinant multimeric vWF containing mutation Ser968Thr in a perfusion system. To investigate structural effects of the mutation, the crystal structure was solved of monomeric Ser968Thr-A3.

Experimental procedures

Construction, Expression, Purification and Characterization of Ser968Thr-A3

Mutation Ser968Thr was introduced in the isolated A3 domain using the Quikchange method (Stratagene, La Jolla CA, USA) and plasmid pET15b-A3 that contains vWF residues 920– 1111¹⁴. The presence of the mutation was confirmed by sequencing.

Ser968Thr-A3 was expressed in *E. coli* BL21(DE3). Bacteria were cultured in LB medium containing 10 g/l peptone, 5 g/l yeast extract and 10 g/l NaC in 1 litre flasks. At a cell density of OD₆₀₀ 1.6 induction was started by the addition of isopropyl- β -D-galactopyranoside (0.5 mM final concentration). Bacteria were cultured for an additional 3 hours, collected by centrifugation and stored at –20 °C. Ser968Thr-A3 was purified according to a procedure published by Huizinga *et al.*¹⁴.

Construction, Expression, Purification and Characterization of Ser968Thr-vWF

Mutation Ser968Thr was introduced in multimeric vWF using the Quikchange method as described before⁷. Briefly, the mutation was introduced into mutagenesis plasmid pBSvWF-NC containing vWF residues 940 to 1113, generating pBSvWF-NC-Ser968Thr, and the presence of the mutation was confirmed by sequencing. The NheI – Csp45I fragment of pBSvWF-NC-Ser968Thr was ligated with NheI – Csp45I digested pNUTvWFcas2, generating plasmid pNUTvWFcas2-S968T.

Ser968Thr-VWF was stably expressed in baby hamster kidney cells that overexpress furin, necessary for proper removal of vWF propeptide^{5; 15}. Cells were cultured in serum-free medium.

Ser968Thr-VWF was purified by immuno-affinity chromatography using monoclonal antibody RU8, which is directed against the D4 domain⁵. Ser968Thr-VWF was eluted in 50 mM Tris, 100 mM NaCl pH 7.4 and vWF-containing fractions were stored at –20 °C.

The vWF concentration was determined by a sandwich ELISA using polyclonal α -vWF and horseradish peroxidase (HRP) conjugated polyclonal α -vWF (DAKO, Glostrup, Denmark) for immobilization and detection, respectively⁵. Normal pooled plasma from 40 healthy donors was used as a reference.

The vWF multimeric structure was analyzed by agarose gel electrophoresis followed by Western blotting as described by Lawrie *et al.* ¹⁶.

Binding of monoclonal antibody (MoAb) RU5 to vWF was analyzed as described before with a few modifications ⁷. Microtiter-plate wells (Costar, Cambridge MA, USA) were coated with 2.5 µg/ml polyclonal α-D'D3 ¹⁷ in 50 mM carbonate buffer pH 9.6 (3 h, 20 °C). Wells were washed with PBS/0.1% Tween-20 and blocked with 3 % BSA in PBS/0.1% Tween-20 (1 h, 37 °C). Wells were incubated with 1 µg/ml vWF in mock medium (1 h, 37 °C). After washing, 2 µg/ml RU5 in PBS/0.1% Tween-20 containing 3% BSA was added (1 h, 37 °C). Wells were washed and incubated with HRP conjugated rabbit-anti-mouse antibody (DAKO, Glostrup, Denmark) diluted 1:2500 in PBS/0.1% Tween-20 containing 3% BSA (1 h, 37 °C). O-phenylenediamine was used as substrate for detection.

Solid-State Collagen-Binding Assay

VWF binding to fibrillar human placenta collagen type III (Sigma chemical CO., St. Louis MO, USA, cat. No. C-4407) was studied in a solid-state collagen-binding assay as before ^{7; 17}. Collagen was coated in microtiter plate wells at a concentration of 50 µg/ml in 20 mM sodium phosphate pH 7.4 by centrifuging the microtiter-plate 15 minutes at 1500 rpm in a table-top centrifuge. After blocking with 3% BSA in PBS/0.1% Tween-20, expression medium containing vWF was added at indicated concentrations (1 h, 37 °C). After washing with running tap water, wells were incubated with horseradish peroxidase conjugated anti-vWF antibody (DAKO, Glostrup, Denmark) in PBS/0.1% Tween-20 containing 3% BSA (1 h, 37 °C). O-phenylenediamine was used as substrate for detection. The binding-isotherms for vWF-collagen interaction were fitted with a 1:1 interaction model $Y_{eq} = Y_{eq,max} * [vWF] / (K_D + [vWF])$, in which Y represents the amount of bound vWF.

Platelet Adhesion to Ser968Thr-vWF under Flow

Human placenta collagen type III coated Thermanox[®] coverslips were prepared as described before ^{18; 19}. Citrated plasma was depleted from endogenous vWF by 3 passages over an immuno-affinity column using monoclonal antibody RU2 that is directed against the vWF-A2 domain ^{20; 21}. Residual endogenous vWF was less than 1% (data not shown). Reconstituted blood was prepared from vWF depleted plasma by adding recombinant vWF (8 µg/µl), washed red blood

cells (40 % (v/v) final concentration) and platelets (2×10^5 cells/ μl) from a blood group O⁺ donor^{22, 23}. Perfusion, using prewarmed perfusate, was done in a miniaturized linear flow perfusion system at a wall-shear rate of 1600 s^{-1} (5 min., 37 °C)¹⁹. Coverslips were stained with May-Grünwald/Giemsa²⁴ and platelet adhesion was evaluated using a light microscopy at 400 fold magnification connected to an Image Analyzer (AMS 40-10, Saffron Walden, UK) and the program Optimas 6.0 (Optimas corporation, Washington, USA). Twenty fields perpendicular to the flow axis at the center of each coverslip were analysed, and platelet adhesion was expressed as a percentage of the covered surface area. As positive and negative control, washed red blood cells and platelets were added to the platelet-donors plasma or to vWF-depleted plasma, respectively. Each data point represents the mean \pm SD of at least three experiments in triplicate.

Crystallization, Data Collection and Processing

Crystals of Ser968Thr-A3 were grown by the hanging-drop vapor-diffusion method at 4 °C using a precipitant solution consisting of 27 % (v/v) PEG 3000, 0.2 M sodium acetate pH 4.6, 0.1 M Tris/HCl pH 8.5 and a protein concentration of 6.5 mg/ml. Crystals that were obtained after 30 days. The crystals were soaked in cryoprotectant containing 30% (m/v) PEG 3000, 0.2 M sodium acetate pH 4.6, 0.1 M Tris/HCl pH 8.5, 15% (v/v) glycerol for 1 - 2 minutes and snap frozen in liquid nitrogen. Diffraction data were collected at the European Synchrotron Radiation Facility (Grenoble, France) on beam line ID14-EH3. Diffraction data were processed using the programs DENZO and Scalepack²⁵. Diffraction data statistics are summarized in Table I.

Structure Determination and Refinement

The structure was solved by molecular replacement using the program CNS²⁶ with the structure of [wt-A3](#)¹⁴ as a search model. Two Ser968Thr-A3 molecules were identified in the asymmetric unit, denoted *A* and *B*. Rebuilding using O²⁷ and positional- and B-factor refinement using CNS were performed until convergence. Non-crystallographic symmetry restraints were applied in the initial stages of refinement. Cross validation was used throughout refinement using a 5% test set of reflections. Refinement used the maximum-likelihood algorithm²⁸ and bulk-solvent correction was applied. Water molecules were placed in difference electron-density peaks if the peak height was at least 3.0σ and the distance to a hydrogen-bond donor or acceptor was 2.7-3.2 Å. Water

molecules with a B-factor above 100 \AA^2 were rejected. The final model was analyzed with PROCHECK²⁹ and WHATIF³⁰. Refinement statistics are summarized in Table I.

Results

Characterization of Ser968Thr-vWF

Since vWF binding to collagen is dependent on the multimer distribution and the conformation of the A3 domain, the multimeric pattern and binding of conformation specific MoAb RU5 to Ser968Thr-vWF were analyzed. The multimer distribution of Ser968Thr-vWF was similar to wt-vWF (data not shown), indicating proper post-translational processing. Binding of conformation dependent monoclonal antibody RU5 to Ser968Thr-vWF was similar to binding to wt-vWF (figure 1), suggesting that the mutation does not disrupt the overall conformation of the A3-domain.

Figure 1: Binding of monoclonal antibody RU5 to Ser968Thr-vWF. VWF was immobilized in microtiter plate wells via polyclonal α D'D3 and was incubated with RU5. Bound RU5 was detected as described under "Experimental Procedures". Wild-type vWF and Δ A3-vWF, which lacks the A3 domain⁵, were used as a positive and negative control, respectively. Binding of RU5 to vWF mutants is expressed as a percentage of wt-vWF. Each data-point represents the mean \pm SD of two independent measurements.

Collagen binding of Ser968Thr-vWF was evaluated in a solid-state collagen-binding assay (figure 2). Wild-type vWF bound saturably and concentration dependent to collagen with a dissociation constant of $1.3 \mu\text{g/ml}$. As expected, binding of Δ A3-vWF to collagen was markedly reduced with a maximal binding of 23 % at a concentration of $10 \mu\text{g/ml}$. Binding of Ser968Thr-vWF to collagen was saturable and concentration dependent. At $10 \mu\text{g/ml}$, the maximum binding Ser968Thr-vWF to collagen type III was 10 % reduced compared to wt-vWF while the dissociation constant was increased to $1.4 \mu\text{g/ml}$. Differences between Ser968Thr-vWF and wt-vWF in binding to collagen are not significant.

Figure 2: Binding of Ser968Thr-vWF to collagen type III in a solid-state collagen-binding assay. Fibrillar human placenta collagen type III was coated in microtiter plate wells. Wells were incubated with vWF at a concentrations indicated and bound vWF was detected as described under “Experimental Procedures”. Δ-A3 vWF was used as a negative control. Bound vWF is expressed as a percentage of wt-vWF. Each data point represents the mean \pm SD of three experiments performed in duplicate.

The effect of mutation Ser968Thr in platelet adhesion to a collagen type III coated surface was evaluated in a perfusion system that mimics the *in vivo* situation. To this end, either wt-vWF, ΔA3-vWF or Ser968Thr-vWF was added to vWF-depleted plasma. In each set of experiments, depleted plasma was supplemented with platelets isolated from different healthy donors, yielded a surface coverage of 9.9%, 9.3%, 30.3% and 43.4% for wt-vWF. Although the variation in platelet adhesion is rather high, donor variation has been reported before and was hypothesized to correlate with surface expression of $\alpha_2\beta_1$ on the platelet^{31;32}. Platelet adhesion mediated by ΔA3-vWF and Ser968Thr-vWF was normalized against wt-vWF within each experiment. Platelet adhesion in the presence of these variants was reduced by 88 % and 49 %, respectively (figure 3).

Figure 3: Platelet adhesion on collagen surface mediated by vWF variants. Human placenta collagen type III was coated on Thermanox® coverslips. VWF variants were added at a concentration of 8 µg/ml to reconstituted blood containing endogenous vWF depleted citrated plasma. Platelet coverage was evaluated after 5 minutes perfusion at a wall shear-rate of 1600 s⁻¹.

Crystal Structure of Ser968Thr-A3

Ser968Thr-A3 was purified from *E. coli* and concentrated to approximately 6.5 mg/ml. During concentration a significant fraction of the protein precipitated, suggesting that the mutation may influence the conformation of the A3 domain. Crystals of Ser968Thr-A3 were obtained by hanging-drop vapor-diffusion crystallisation at 4 °C. Crystallographic data statistics of a Ser968Thr-A3 crystal that was measured at the ESRF are summarized in Table I. Two molecules, denoted *A* and *B*, were observed in the asymmetric unit of which one is shown in figure 4A. The structure was refined to a R-factor of 18.2 % and a free R-factor of 22.8 %, contains 279 water molecules and 4 glycerol molecules. Refinement statistics are summarized in Table I. Judged from the Ramachandran plot the models were of good geometry, because 93.8 % of the residues were in the most favored region and 6.2 % in the additional allowed regions.

Figure 4: Crystal structure of Ser968Thr-A3. (A) Crystal structure of one of the Ser968Thr molecules is shown. Ser/Thr⁹⁶⁸ is shown in the structure and is buried just below the surface containing residues that are involved in collagen binding. (B) Superposition of one wt-A3 and one Ser968Thr-A3 model. Except for a small movement of the Trp⁹⁸² side chain, the mutation does not induce local conformational changes.

^c Main chain atoms. Number between parenthesis is from side chain atoms.

^d Average B-factor of the molecules in Å² is given between parenthesis.

The A3 construct contains residues 920 – 1111 of mature vWF, but the N- and C-termini are disordered in the crystal. For molecule *A* we observe residues 925 – 1108 while we see for molecule *B* residues 925 – 1099. In both molecules the Cys923-Cys1109 disulfide bridge that links the N- and C-terminal regions of the domain could not be observed. Possibly the disulfide bridge was broken by the intense X-ray beam of the synchrotron. Breaking of a disulfide bond at the surface of a protein by X-rays has been observed before in other proteins³³. This had the most structural consequences in molecule *B* in which C-terminal residues Leu¹¹⁰⁰ to Ser¹¹¹¹ could not be observed.

Structural Comparison of wt-A3 and Ser968Thr-A3

Superposition of Ser968Thr-A3 molecules *A* and *B* shows variation in the conformation of loops $\alpha 1\beta 2$ (residues 961 – 963), $\beta 3\alpha 2$ (residues 983 – 987) and $\alpha 5\beta 6$ (residues 1078 – 1084). However, a similar variation is observed within wt-A3 models⁷, indicating that these loops are flexible in both wt- and mutant A3. In the proximity of Thr⁹⁶⁸ no variation in the backbone or side chains is observed between molecules *A* and *B*.

To investigate whether mutation Ser968Thr introduces conformational changes in the A3 domain, molecules *A* and *B* of the mutant and eight known wt-A3 models were superimposed^{7; 14; 34}. The overall structure Ser968Thr-A3 and wt-A3 were indistinguishable indicating that the mutation does not induce long-range effects in A3.

In wt-A3, Ser⁹⁶⁸ is located just beneath the surface of the protein in close proximity of residues Ile⁹⁷⁵, Thr⁹⁷⁷, Asp⁹⁷⁹, Val⁹⁹⁷, Glu¹⁰⁰¹, Arg¹⁰¹⁶, Ser¹⁰²⁰ and His¹⁰²³ that are involved in collagen binding⁷. The Ser⁹⁶⁸ side chain adopts two conformations, indicating that there is some flexibility (figure 4B). In one conformation the hydroxyl group points to the interior of the domain, whereas in the other conformation it points to the surface and its hydroxyl group forms a hydrogen bond with the backbone carbonyl oxygen of Val⁹⁸⁰. In both models of the mutant, the hydroxyl group of Thr⁹⁶⁸ points to the interior of the domain and occupies the same position as the inwards-oriented hydroxyl of Ser⁹⁶⁸ in the wild-type protein. This conformation gives some strain due to a short distance of 3.1 Å between the methyl group of the of Thr⁹⁶⁸ side chain and the side chain of Trp⁹⁸². Although the side chain of Trp⁹⁸² moves slightly, the displacement is too small to relief the strain. No conformational changes are observed for residues at the surface of

the domain that are involved in collagen binding. Therefore, apart from the small movement of Trp⁹⁸², mutation Ser968Thr does not introduce local conformational changes.

Discussion

Recently, two related patients have been described who suffer from slightly increased bleeding times¹³. These patients have a mutation in the A3 domain. This mutation, Ser968Thr, is the first identified mutation in the A3 domain that reduces the affinity of vWF for collagen. In the present study we investigated the effect of the mutation multimeric vWF in platelet adhesion in a flow system. In addition, to identify conformational changes induced by the mutation we solved the structure of Ser968Thr-A3.

The multimeric structure of vWF is essential for a proper function, because vWF with a reduced multimeric size has a decreased affinity for collagen³. Multimeric composition of Ser968Thr-vWF was indistinguishable from wt-vWF. Moreover, binding of conformation-dependent, function-inhibiting MoAb RU5 to Ser968Thr-vWF was not reduced compared to wt-vWF. This is in agreement with Ribba *et al.*¹³ who found that the binding of monoclonal antibodies 505 and B200 to Ser968Thr-vWF was normal. These results indicate that mutation Ser968Thr does not destroy the protein by means of post-translational modification or folding. Any observed effects in collagen-binding are therefore due to the (direct) involvement of Ser⁹⁶⁸ in collagen binding.

Collagen-binding was evaluated in a solid-state collagen-binding assay. We found that collagen-binding of Ser968Thr-vWF was not significantly reduced compared to wt-vWF, whereas Ribba *et al.* measured 50 % reduced collagen binding¹³. These authors have expressed vWF in COS-7 cells which do not cleave off the vWF propeptide. We have used vWF expressed in BHK cells that also overexpress furin that removes the vWF propeptide. However, this difference is not likely to cause the observed discrepancy. Another, more significant, difference is that in the study of Ribba *et al.* collagen binding was evaluated using human placenta collagen type I while we have used human placenta collagen type III. Apparently, mutation Ser968Thr has a different effect on different types of collagen.

Whereas mutation Ser968Thr did not significantly reduce the collagen-binding affinity in a solid-state collagen-binding assay, the mutation partially inhibited platelet adhesion to a collagen type III coated surface at high shear stress. This suggests that mutation Ser968Thr may have a different effect under shear compared to static conditions. It may be that mutation Ser968Thr does not influence the affinity under static conditions, but under conditions of shear stress it may shift the affinity to a low state.

In the crystal structure of Ser968Thr-A3 no long- or short-range conformational changes could be observed. This is in agreement with the normal reactivity of conformation dependent MoAb's 505, B200¹³ and RU5 towards Ser968Thr-vWF. However, this does not indicate that there are no conformational changes induced by the mutation. We have hypothesized before that collagen binding by the A3 domain involves an induced-fit model involving residues within loop $\alpha 3\beta 4$ that is close to Ser⁹⁶⁸ and loop $\beta 3\alpha 2$ located somewhat further away⁷. Among wild-type structures loop $\alpha 3\beta 4$ is observed in two conformations, whereas in the mutant only one conformation is observed (data not shown). In the mutant similar flexibility for loop $\beta 3\alpha 2$ was observed as in wt-A3. It may be that the mutation shifts the equilibrium of these loops to the low-affinity conformation, but that during the crystallization process there is preference for one of these conformations. Based on the experimental data it is not conclusive whether the high- or low-affinity conformation crystallizes.

Based on above assumptions we can not exclude that mutation Ser968Thr does not introduce long- or short range conformational changes in the A3 domain, but we are not able to observe these conformational changes in the crystal structure. Our data suggest that under shear conditions mutation Ser968Thr shifts the equilibrium between a high- and a low-affinity conformation and thereby reduces collagen binding.

Summary

Transient interactions of platelet-receptor glycoprotein Ib α (GpIb α) and plasma-protein von Willebrand Factor (VWF) reduce platelet velocity at sites of vascular damage and play a role in haemostasis and thrombosis. Here we present structures of the GpIb α N-terminal domain and its complex with VWF domain A1. In the complex GpIb α wraps around one side of A1 providing two contact areas bridged by an area of solvated charge interaction. The structures explain the effects of gain-of-function mutations related to bleeding disorders and provide a model for shear-induced activation. These detailed insights into the initial interactions in platelet adhesion are relevant for the development of anti-thrombotics.

Results and Discussion

Transient interactions of platelet-receptor glycoprotein Ib α (GpIb α) and immobilized von Willebrand Factor (VWF) mediate rolling of platelets at sites of vascular damage. Rolling reduces platelet velocity and prolongs the contact time with reactive components of the cell matrix. This facilitates platelet-activation and subsequent integrin-mediated firm attachment ¹. Platelet GpIb α and VWF coexist in the circulation, but do not interact at a detectable level unless shear stress is applied or exogenous modulators like the snake venom botrocetin are added ². Four types of congenital bleeding disorders have been defined that are caused by mutations in GpIb α or VWF either enhancing or reducing complex formation. Shear-induced GpIb α -VWF interaction in occluded atherosclerotic arteries or at the surface of ruptured atherosclerotic plaques contributes critically to the onset of arterial thrombosis ³.

GpIb α is the central component of a receptor complex consisting of glycoproteins Ib α , Ib β , IX and V. It anchors the complex to the cytoskeleton and harbors the VWF-binding function in its ~290 N-terminal residues. The VWF-binding site is exposed well above the platelet surface, being connected to a ~45 nm long highly O-glycosylated stalk ⁴. The ~250-kDa VWF protein forms large disulfide-bonded multimers with molecular weights of up to 10 MDa. It is found in plasma and the sub-endothelial cell matrix and is released from storage granules when platelets and endothelial cells are activated. A VWF-multimer acts as bridging ligand between platelets and the cell matrix, through collagen binding by its A3 domain and binding to GpIb α by its A1 domain ⁵.

Although the crystal structure of VWF-A1 is known ^{6; 7} and there is a large body of mutagenesis data ⁸⁻¹⁵, the precise interactions between GpIb α and A1, the mechanism of shear-induced activation and the molecular basis of related bleeding disorders are poorly understood. We present crystal structures of the N-terminal domain of GpIb α (residues 1-290) and its complex with the VWF-A1 domain (residues 498-705; VWF residue numbering used starts at the first residue of the mature subunit, addition of 763 converts the numbering to that of preproVWF) (Table 1). We expressed recombinant GpIb α with the mutations N21Q and N159Q to remove N-glycosylation sites. Crystallization of the complex required the use of gain-of-function mutants GpIb α -M239V and A1-R543Q that are associated with platelet-type and type 2B von Willebrand diseases and cause an enhanced affinity for complex formation (K_d = 5.8 nM).

The crystal structure of the von Willebrand factor-binding domain of GpIb α displays an elongated curved shape (figure 1) that is typical for proteins containing leucine-rich repeats (reviewed in ¹⁶). Eight short leucine-rich repeats, seven of which were predicted based on the amino-acid sequence, make up the central region of the molecule. Flanking sequences, which are conserved among numerous extra-cellular proteins including the other members of the GpIb-IX-V complex, cap the leucine-rich repeats. The N-terminal sequence forms a 14-residue β -hairpin delimited by a conserved disulfide bond between Cys4 and Cys17. The tip of the β -hairpin, which we refer to as β -finger, protrudes from the protein surface and is disordered in one of the two molecules in the asymmetric unit. The C-terminal sequence, up to residue 267, contains a 9-residue α -helix and four short 3_{10} -helices. The anionic region beyond residue 267 was not visible in the electron-density and was not modeled. Conserved disulfide bonds between Cys209 and Cys248 and between Cys211 and Cys264 stabilize the irregular fold of the C-terminal region. Residues 227 to 241 project from the concave face of the molecule forming a highly flexible loop that shows disorder in both molecules in the asymmetric unit. Sequence alignment of C-terminal flanking regions ¹⁷ shows that the protruding loop is not a conserved feature in this domain-family.

Figure 1: Structures of the VWF-binding domain of GpIb α and the complex of GpIb α with the A1 domain of VWF. Ribbon representation of GpIb α . The N-terminal β -hairpin, called ' β -finger', is colored blue; the eight leucine-rich repeats are green. The C-terminal flanking region is colored red and contains a disordered loop (residues 227-241), called ' β -switch'. Disulfide bridges are indicated in yellow ball-and-stick representation.

The crystal structure of the complex GpIb α – VWF-A1 shows that the globular A1 domain interacts with the concave face of GpIb α (figure 2). The interaction surface is extended, but discontinuous, comprising two distinct areas of tight interactions (figure 3A). The first and most extensive contact site is located near the top of A1 and buries a solvent accessible surface of $\sim 1700 \text{ \AA}^2$. In this contact site leucine-rich repeats 5 to 8 and the C-terminal flank of GpIb α interact with A1 helix $\alpha 3$, loop $\alpha 3\beta 4$ and strand $\beta 3$ (figure 3A and B). The second and smaller contact site buries a surface of $\sim 900 \text{ \AA}^2$ and involves interactions of the N-terminal β -hairpin and the first leucine-rich repeat of GpIb α with loops $\alpha 1\beta 2$, $\beta 3\alpha 2$, and $\alpha 3\beta 4$ at the bottom-face of the A1 domain. As for the native structure of GpIb α , we did not observe electron density for the C-terminal anionic region of GpIb α in the complex. This is surprising since this region affects rolling of GpIb α expressing CHO cells over VWF¹⁸, but is consistent with our observation that the anionic region has no significant effect on binding to VWF-A1.

Figure 2: Stereo view of a ribbon representation of the complex GpIb α -A1. GpIb α is shown in green and A1 in blue with mutations GpIb α -M239V and A1-R543Q shown in red and the disulfide bridge in A1 shown in yellow ball-and-stick representation. The β -switch of GpIb α adopts a β -hairpin structure that aligns with the central β -sheet of A1.

click on this link for rotating image

Figure 3: A: Stereo representation of residues at the A1-GpIb α interface, excluding residues located in the β -switch of GpIb α and strand β 3 of A1. Residues involved in inter-molecular contacts shorter than 4.0 Å are shown in stick representation; they form two sites of tight contact separated by an area of solvated interactions. Remarkably, Lys549, Trp550 and Arg571 of A1 contacting the β -finger and the first leucine-rich-repeat of GpIb α are disordered showing reduced electron density for their side chains. B: Close-up of the β -switch and its interaction with strand β 3 of A1. Main-chain hydrogen bonds are shown by dotted lines. Amino acids known to have gain-of-function mutations related to platelet-type von Willebrand disease have red labels and likely induce β -hairpin formation in the β -switch of GpIb α .

The flexible loop 227-241 in the C-terminal flank of GpIb α undergoes a conformational change upon complex formation. In the complex this loop, that we call the β -switch, forms a 16-residue β -hairpin that extends from residues 227 to 242 and aligns with strand β 3 of A1 (residues 562-566) forming a continuous β -sheet shared between the two

molecules (figure 3B). Interestingly, gain-of-function mutations related to platelet-type von Willebrand disease, are all found in the β -switch. The specific mutation M239V that we used to obtain crystals of the complex, enhances binding ~ 3 -fold and is located in the β -switch strand that directly hydrogen bonds to $\beta 3$ of A1. Val239 provides two intermolecular main-chain hydrogen bonds and its side-chain contacts Tyr600 of helix $\alpha 3$ in A1. Based on the structure similar interactions with methionine in the wild-type protein may be expected. Other known gain-of-function mutations include G233V, that like M239V is detected in patients with platelet-type von Willebrand disease^{19; 20}, and V234G, D235V and K237V that have been identified by site-directed mutagenesis^{14; 15}. Four of the five gain-of-function mutations involve amino-acid substitutions known to stabilize β -hairpin structures by introducing a C β -branched residue in the strands (G233V, M239V and K237V) or a glycine residue in the tight turn (V234G)²¹. The mutation M239V increases the association rate three-fold, and hardly affects the dissociation rate, which is consistent with stabilization of the β -hairpin priming the mutant GpIb α for A1-binding. Unclear at this stage is how D235V, at the second position in the tight turn, induces β -hairpin formation and enhances the binding affinity. However, all five mutations support an indirect mechanism by influencing the conformation, because the side chains have either no or few direct contacts to A1 in the complex. Other valine substitutions in this region (K231V, Q232V, A238V and T240V) that reduce binding affinity¹⁵ may be explained in part by steric hindrance (Q232V and A238V) and loss of a hydrogen bond with Asp560 of A1 (T240V). Overall, we conclude that the conformational equilibrium of the β -switch of GpIb α is a critical factor in the precisely balanced affinity of the interacting partners.

Gain-of-function mutations related to type 2B von Willebrand disease cluster at the bottom face of A1 (figure 4) adjacent to the interaction site with the β -finger of GpIb α . Type 2B mutation R543Q that we used in the structure determination of the complex is located 20 Å away from the interaction site. It causes a ~ 2.5 fold increase in binding affinity of the isolated A1 domain. However, the affinity of the wild-type A1 domain ($K_d \sim 30$ nM) is already much higher than the affinity of multimeric VWF, for which we do not detect any binding up to a concentration of 150 nM. Similarly, other studies have indicated that the affinity depends on the length of the A1-containing VWF fragment employed (see e.g. ref.⁹). Therefore, the A1 domain used for crystallization lacks key structural elements that suppress GpIb α binding in multimeric VWF. In the crystal structure of the wild-type domain⁷ the N- and C-termini of A1 approach the β -finger interaction site (figure 4), suggesting that longer

terminal peptides could shield the binding site of the β -finger in multimeric VWF. Type 2B mutations likely destabilize a network of interactions observed between the bottom face of A1 and its terminal peptides in the wild-type A1 structure ⁷, thereby making the binding site accessible. In the complex we indeed observe a displacement of the termini away from the interaction site and a partial disordering of the N-terminus. In comparison, the homologous integrin I-type domains bind their ligands at a different site and the large conformational changes observed upon ligand binding in I-domains ²² do not occur in A1. The mechanism of affinity modulation in the A1 domain is therefore different from that of I-type domains and likely involves conformational changes at the N- and C-termini. Shear stress may induce these changes in immobilized VWF causing activation in the platelet adhesion process.

Figure 4: Structural changes at the N- and C-terminal side of VWF-A1. The bottom face of the A1 domain, as observed in the complex with GpIb α , is shown in space-filling representation with the N- and C-terminal peptides shown as C α -traces in yellow. The position of the β -finger of GpIb α is given by a C α -trace in green. In red we indicated the C α -traces of the N- and C-terminal peptides of the uncomplexed, wild-type A1 domain ⁷. Residues with known gain-of-function mutations, yielding a type 2B von Willebrand disease phenotype, are either shown in ball-and-stick representation in the (wild-type) N- or C-terminal peptides or colored blue in the space-filling model of the bottom face. In full-length VWF flanking peptides of A1 possibly shield the binding site of the β -finger of GpIb α .

The electrostatic surface-potentials of GpIb α and A1 are characterized by large patches of opposite charge at the GpIb α -A1 interface that induce long-range electrostatic attraction (figure 5). Besides the positively charged patch at the interface, A1 also shows a large negatively charged patch on the opposite side of the domain. Possibly, the asymmetric charge distribution on A1 helps in steering the long-range interactions. Crystal structures of P- and E-selectins bound to sialyl Lewis^x or a sulfated peptide from PSGL-1, components that mediate rolling of leukocytes over inflamed endothelium, also indicated dominant

electrostatic interactions²³. However, in the GpIb α -A1 complex, residues making up the charge potentials at the interface are not involved in direct contacts, but are either fully or partially solvated. Thus, it appears that the surfaces of A1 and GpIb α are organized for long-range electrostatic attraction avoiding the energetically unfavorable desolvation of charged residues²⁴ in the formation of the final complex.

Figure 5: Electrostatic surface potentials of the A1 domain of VWF and GpIb α . Potentials were calculated for the individual molecules. The surface is colored blue for potentials of $> 6\text{kT/e}$ and red for potentials of $< -6\text{kT/e}$. The C α -traces of the partner molecules in the complex are shown in white for clarity. The areas of large electrostatic potentials at the interface of A1 and GpIb α coincide with the region of loose, solvent-mediated contacts between the two molecules. Calculations were performed with GRASP²⁵.

The Bernard-Soulier syndrome and type 2M von Willebrand disease are characterized by loss of function mutations in GpIb α and VWF-A1, respectively. Loss of function mutations in the VWF-binding domain of GpIb α occur at buried sites (L57F, C65R, L129P and A156V) or in a disulfide bond (C209S) and likely disturb the structural integrity of the domain causing a reduction in binding affinity. Numerous, loss-of-function mutations, detected in von Willebrand disease type 2M patients⁸ or identified by site-directed mutagenesis⁹⁻¹³ scatter throughout the A1 domain. Sixteen loss-of-function mutations involve residues in or directly next to the GpIb α binding site, whereas 10 occur at buried positions inside the A1 domain, and are likely to disrupt the A1 structure or induce conformational changes to A1 incompatible with binding to GpIb α . The remaining 14 mutations are scattered

over the surface outside the observed GpIb α binding site and cannot be explained based on the structure of the A1-GpIb α complex.

Our data suggest that GpIb α and VWF are attracted by long-range electrostatic interactions and indicate two contact sites in the final complex, which present primary targets for development of drugs for the treatment or prevention of arterial thrombosis. Interaction at the larger contact site depends on conformational changes in the β -switch of GpIb α , whereas the second, smaller site requires most likely dislodging of the termini of the A1 domain uncovering the site of interaction. Mutations that cause gain-of-function diseases favor the bound conformation at both contact sites. It is conceivable that under physiological conditions shear stress on immobilized VWF displaces the termini of the A1 domain exposing the second binding site and hence enhances platelet association to the site of vascular damage.

Methods

Protein expression and purification

GpIb α residues 1 to 269 and 1 to 290 preceded by the signal peptide and fused to a C-terminal (His)₆ or Arg-(His)₆ sequence, respectively, were cloned into expression vector pCDNA3.1. The QuikChange kit from Stratagene was used to introduce mutations N21Q and N159Q, removing two N-glycosylation sites, and mutation M239V, a platelet-type von Willebrand disease mutation. Proteins were expressed in stable BHK cell-lines. BHK cells were cultured in Dulbecco's MEM/ F-12 Ham medium containing 5% fetal calf serum. During protein production serum was replaced by 1% Ultrosor G (Gibco). GpIb α fragments were purified from expression medium by Ni²⁺/NTA chromatography followed by anion exchange (MonoQ) and gel filtration (Superdex 200). Typically, 1 mg of GpIb α could be purified from 1 liter of medium. The protein was concentrated to ~7 mg/ml in the gel filtration buffer (50 mM NaCl, 20 mM Tris/HCl pH 8.0). Anion exchange of wild-type and mutant GpIb α (1-290) proteins yielded four base-line separated peaks. Electro-spray mass spectroscopic analysis showed that these peaks contain GpIb α modified by sulfation at 0, 1, 2 or 3 sites, likely tyrosine residues in the anionic region (data not shown). Fully sulfated GpIb α was used for crystallization experiments.

Wild-type VWF-A1 domain residues 498 to 705 and mutant A1 R543Q were cloned in expression vector pPIC9 and over-expressed in *Pichia pastoris* strain GS115, according to the

Invitrogen manual. After 3 days of induction expression medium was collected and dialyzed against standard buffer (25 mM Tris, 100 mM NaCl, pH 7.8). The protein was purified on heparin Sepharose, followed by gel filtration (Superdex 200). It was dialyzed against standard buffer and concentrated to ~4 mg/ml.

Multimeric recombinant VWF was produced and purified according to a published procedure²⁶.

Crystallization

Crystals were grown using the hanging-drop vapor-diffusion technique. GpIb α (N21Q, N159Q) crystals were obtained at 28 °C by mixing 1 μ l of protein solution and 1 μ l reservoir solution (1.8 M ammonium sulfate, 0.2 M lithium sulfate and 100 mM CAPS pH 8.2). Before flash cooling, crystals were transferred to a cryo-protective solution (25% (w/v) PEG 3000, 200 mM NaCl, 100 mM Tris pH 8.2 and 15% (v/v) glycerol). GpIb α crystals have space group *C2* with cell constants: $a = 121.5$ Å, $b = 54.5$ Å, $c = 101.8$ Å, $\beta = 103.7^\circ$, and contain two molecules per asymmetric unit.

Crystals of a complex of GpIb α mutant (N21Q, N159Q, M239V) and A1 mutant (R543Q) were obtained at 4 °C by mixing 1 μ l protein solution containing a 1:1 molar ratio of A1 and GpIb α and 1 μ l precipitant solution (10% (w/v) PEG 3000, 200 mM NaCl and 100 mM MES pH 5.5). Before flash cooling crystals were transferred to precipitant solution containing 20 % (v/v) glycerol. Crystals have space group *P6₁* with cell constants: $a = b = 89.8$ Å, and $c = 124.6$ Å, and contain one complex per asymmetric unit.

Structure determination

Data were collected on beam line ID14-2 at the ESRF and on beam line X11 at the EMBL outstation (DESY). Data were processed with DENZO and SCALEPACK²⁷. Structures were solved in conjunction by molecular replacement. A model of A1⁷ was placed in the unit cell of the complex using CNS²⁸. Solvent flattening with CNS revealed β -strands of GpIb α leucine-rich repeats. A mask was constructed around the putative GpIb α molecule and electron density inside the mask was used for molecular replacement with AMoRe²⁹. This identified two molecules in the asymmetric unit of the GpIb α crystal. Improved electron density obtained after density modification and phase extension to 2.5 Å was used for model building with O³⁰. The model was refined at 1.8 Å resolution using CNS and then used together with the model of A1⁷ as the starting point for refinement of the GpIb α -A1 complex.

Refinement included bulk solvent correction and calculation of R_{free} using 5% of the reflections. Diffraction data and refinement statistics are given in Table I. The structures of GpIb α and the GpIb α -A1 complex have been deposited in the PDB with ID numbers [1M0Z](#) and [1M10](#), respectively.

Biacore analysis

Binding studies were performed on a Biacore 2000 (Biacore AB, Uppsala Sweden). GpIb α monoclonal antibody 2D4 was immobilized on CM5-sensorchips by amine-coupling as instructed by the supplier. A control channel was activated and blocked by using the amine-coupling reagents in the absence of protein. Proteins were dialysed to standard Biacore buffer (150 mM NaCl, 0.005% (v/v) Tween-20 and 25 mM HEPES pH 7.4) and analyzed at 25 $^\circ\text{C}$.

GpIb α (150 nM) was injected for 1 minute, followed by a 2 minute association phase of A1 (5-100 nM) or multimeric recombinant VWF (150 nM). Finally, standard buffer was injected and the dissociation phase was recorded for 5 minutes. The sensor-chip was regenerated by injections of 50 mM triethylamine, 10 mM sodium formate pH 2.0 containing 150 mM NaCl and another injection of 50mM triethylamine. Each interaction was analyzed at five different VWF-A1 concentrations. Data evaluation was performed with Bia evaluation software (Biacore AB) using a 1:1 Langmuir model with baseline drift to compensate for the slow release of GpIb α from 2D4. Control experiments included immobilization of GpIb α *via* His-tag antibody 3D5 (Novagen), which excluded artifacts caused by antibody 2D4, and a comparison of glycosylated and non-glycosylated mutant GpIb α to confirm that glycosylation has no effect on binding.

Acknowledgements

We thank D. Westra and M. Bulsink for contributions to the early stages of the project; P. Lenting and E. Westein for technical assistance with Biacore measurements; H. Deckmyn (Kortrijk, Belgium) for generously supplying monoclonal 2D4; and beam line scientists at the ESRF in Grenoble and the EMBL outstation in Hamburg for assistance during data collection. We acknowledge financial support of the "European Community - Access to Research Infrastructure Action of the Improving Human Potential Programme" to the EMBL Hamburg Outstation, the Dutch Heart Foundation and the council of Medical Sciences of the Netherlands Organization for Scientific Research.

Summary

Thrombus formation is initiated by platelet arrest at sites of vascular injury. This process is dependent on von Willebrand Factor (vWF) and requires the interaction of its A1 domain with glycoprotein (Gp) Ib α on the platelet. VWF must be activated before GpIb α binding occurs, either via surface adsorption, vWD type 2B mutations or exogenous agonists.

We have investigated the binding kinetics of wild type- and vWD mutant Arg543Gln-vWF and of wild type- and Arg543Gln-A1 to GpIb α . In contrast to wt-vWF, wt-A1 bound spontaneous to GpIb α indicating that the isolated A1 domain is already activated. The effect of mutation Arg543Gln in the isolated A1 domain is small compared to the effect in vWF.

We have solved three crystal structures of wt-A1 and three crystal structures of Arg543Gln-A1 and compared their conformation with the A1•GpIb α complex, Ile546Val-A1 and published wt-A1 structures. In wt-A1, the N- and C-terminal flanking peptides approach the GpIb α binding site at the bottom of A1. Probably in vWF the peptides overlap the GpIb α binding site. In type 2B-A1 the peptides adopt a different conformation and do not overlap the GpIb α binding site. Probably this conformation resembles vWF under conditions of shear after binding to the vascular matrix.

In conclusion, these crystallographic data confirm the activation mechanism of A1 involving conformational changes in the N- and C-terminal flanking peptides. These conformational changes switch the A1 domain from a low- to a high affinity state by opening the GpIb α binding site at the bottom face of the domain.

Introduction

Von Willebrand factor (vWF) is a multimeric plasma glycoprotein that is essential for platelet adhesion at sites of vascular injury. The primary function of vWF is to form a molecular bridge between collagen from the subendothelial connective matrix of a damaged vessel wall and the platelet receptor glycoprotein (Gp) Ib-IX-V complex.

Mature vWF^a consists of 2050 amino-acid residues in five different domain subtypes in the order D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK. After synthesis, vWF dimerisation occurs at the cystine knot (CK) domain and multimerisation at the D3 domain ¹. A vWF multimer can contain up to 80 monomers ². Multimerisation of vWF is essential for a normal function, because low vWF multimers have a decreased affinity for their ligands ³. The A1 domain, spanning residues Cys⁵⁰⁹ - Cys⁶⁹⁵, contains the GpIb α binding site ^{4; 5}.

In normal haemostasis the vWF-A1 domain does not bind spontaneously to GpIb α . *In vivo*, immobilisation of vWF to the subendothelial connective tissue induces GpIb α binding, especially under conditions of high shear ⁶. *In vitro*, binding to GpIb α can be induced by modulators like the toxin botrocetin ⁷ from *Bothrops jararaca* or the antibiotic ristocetin ⁸ from *Nocardia lurida*. Botrocetin and ristocetin bind to different regions in A1 ⁹. Ristocetin interacts with the C-terminal flanking peptide of A1 ^{10;11} and mimics shear-induced GpIb α binding ¹². However, the activation mechanism of vWF at a molecular level is a poorly understood process.

Recently we have solved the crystal structure of the A1 domain in complex with the 290 amino-terminal residues of GpIb α that contains the A1-binding site ¹³. A1 and GpIb α have an extended, but discontinuous, interaction site. There are two areas of tight interactions. The first interaction site is located near the top of A1 and involves residues in helix α 3, loop α 3 β 4 and strand β 3. The second interaction site comprises several loops at the bottom-face of A1. We hypothesized that in inactive vWF the second interaction site is blocked by the N- and C-terminal flanking peptides and that GpIb α binding may be induced by a conformational change in these peptides

In patients, so-called von Willebrand disease (vWD) type 2B mutations at the bottom of the A1 domain, or in its flanking peptides, also induce spontaneous GpIb α binding and cause platelet clumping, thrombocytopenia, low plasma vWF levels and a bleeding tendency. A mechanism by which vWD type 2B mutations activate the A1 domain has been proposed

by Celikel *et al.*¹⁴. In this model, mutation Ile546Val at the bottom of A1 induces a conformational change in hairpin $\beta 2\beta 3$ that is part of the GpIb α -binding site, but is located close to the top of A1. Although in the A1•GpIb α complex minor conformational changes are observed for loop $\beta 2\beta 3$, larger conformational changes occur in the N- and C-terminal flanking peptides¹³.

In this study we have solved crystal structures of three different crystal forms of either wt-A1 and gain-of-function mutant Arg543Gln-A1, yielding eleven new models. Together with the previously published wt- and type 2B mutant A1 structures this set of structures was used for the analysis of conformational changes in A1 required for activation. Observed conformational changes in the N- and C-terminal flanking peptides explain the activation mechanism of vWF resulting in GpIb α binding.

Methods

Construction of *Pichia pastoris* expressing A1

VWF residues 498 – 705 (VWF residue numbering used starts at the first residue of the mature subunit, addition of 763 converts the numbering to that of preproVWF) containing the A1 domain, were cloned into expression vector pPIC9 (Invitrogen, Breda, The Netherlands). The wt- and Arg543Gln-A1 domains were amplified by PCR from plasmids pNUT-vWFCas and pNUT-vWF-Arg543Gln^{15; 16}, respectively using primers **GGACTCGAGAAAGAGAG-GCTGAAGCTGACATCTCGGAACCGCCGTTGC** and **GCGGCCGCTTAAGTAGGA-GGAGGGGCTTCAGGGG** (sequences in bold are from vWF, other sequences are from pPIC9) and PWO polymerase (Roche, Almere, The Netherlands). The PCR product was extended by an additional adenine nucleotide using Taq polymerase (Enzyme Technologies, United Kingdom), ligated into pCR2.1-TOPO vector (Invitrogen, Breda, The Netherlands) generating TOPO-A1 and sequenced (Hubrecht laboratories, Utrecht, The Netherlands). TOPO-A1 was digested with restriction enzymes XhoI and NotI and the fragment containing A1 was ligated with XhoI – NotI digested plasmid pPIC9 using Rapid ligase (Roche, Almere, The Netherlands) generating expression vectors pPIC9-vwf498/705 and pPIC9-vwf498/705-Arg543Gln.

^a Throughout the text: vWF represents multimeric vWF and A1 represents the isolated A1 domain.

The expression vectors were linearised by digestion with BglII or SacI and transformed to *Pichia pastoris* strain GS115. Twenty colonies were picked and grown in 4 ml BMGY medium, containing 1 % yeast extract, 2 % peptone, 100 mM potassium phosphate pH 6.0, 1.34 % yeast nitrogen base, 4×10^{-5} % biotin and 1 % glycerol, for 72 hours. Cells were harvested by centrifugation and grown in 4 ml BMMY medium, containing 1 % yeast extract, 2 % peptone, 100 mM potassium phosphate pH 6.0, 1.34 % yeast nitrogen base, 4×10^{-5} % biotin and 0.5 % methanol, for an additional 72 hour. Expression medium was collected by centrifugation and A1 expression levels were analysed by ELISA. To this end, expression medium was diluted 10, 100 or 1000 fold in 50 mM carbonate buffer pH 9.6 and coated in microtiter plate wells at 37 °C for 3 hours. Wells were washed with PBS/0.1% Tween-20, blocked with 1 % protifar (Nutricia, Zoetermeer, The Netherlands) in PBS/0.1% Tween-20 (1/2 h, 37 °C), washed with running tap-water and incubated with HRP conjugated polyclonal α -vWF (DAKO, Glostrup, Denmark) diluted 1:2500 in PBS/0.1% Tween-20 containing 1 % protifar (1 h, 37 °C). O-phenylenediamine was used as substrate for detection. Three clones displaying the highest expression were stored in 20 % glycerol stocks at –80 °C.

Expression and purification of vWF-A1

For large-scale expression of A1, a single colony was inoculated in 6 * 300 ml BMGY medium and grown for 90 h at 30 °C. Cells were collected by centrifugation, suspended in 6 * 300 ml BMMY medium and grown for 72 h at 30 °C. Expression medium was collected by centrifugation, filtered (0.22 μ m) and dialysed against 20 volumes of a buffer containing 25 mM Tris, 100 mM NaCl, pH 7.8 (o/n, 4 °C). After filtration A1 was loaded on a 12 ml heparin sepharose column (Amersham Pharmacia Biotech, Roosendaal, The Netherlands). The column was extensively washed with 25 mM Tris, 200 mM NaCl, pH 7.8. and A1 was eluted with 25 mM Tris, 1 M NaCl, pH 7.8. A1 containing fractions were pooled and purified over a HiLoad 16/60 Superdex 200 prep grade column (Amersham Pharmacia Biotech, Roosendaal, The Netherlands) in 25 mM Tris, 250 mM NaCl, pH 7.8. Fractions were analysed by SDS-PAGE, pooled, dialysed against 25 mM Tris, 100 mM NaCl, pH 7.8 (o/n, 4 °C), concentrated to 4-4.5 mg/ml and stored at –20 °C. Typically, 6 mg of purified A1 was obtained from 1 l expression medium. The purified and concentrated A1 domain migrated on a non-reducing SDS-PAGE gel as a single band with minor contaminating bands.

Expression, purification and characterisation of wt- and Arg543Gln-vWF

VWF was stably expressed in baby hamster kidney cells overexpressing furin required for proper removal of vWF propeptide^{17, 18}. Cells were cultured in serum-free medium. VWF was purified by immuno-affinity chromatography¹⁷ and stored in 50 mM Hepes, 100 mM NaCl pH 7.4 at -20 °C until use. The vWF concentration and multimeric structure were determined by sandwich ELISA¹⁷ and agarose gel electrophoresis¹⁹, respectively.

Expression, purification and characterisation of GpIb α

GpIb α was stably expressed in baby hamster kidney cells that were cultured in serum free medium. GpIb α was purified as described before¹³ and migrated as a single 25 kDa band on a non-reducing SDS-PAGE gel.

Surface Plasmon Resonance Analysis

Binding studies were performed using surface plasmon resonance (SPR) in a Biacore 2000 biosensor (Biacore AB, Uppsala Sweden). Monoclonal antibody 2D4 directed against GpIb α was immobilized on a CM5-sensorchip using the amine-coupling kit as instructed by supplier, yielding 3300 reference units (RU) that corresponds with 22 fmol/mm² immobilised 2D4. A control channel was activated and blocked using the amine-coupling reagents in the absence of protein. Proteins were dialyzed against standard buffer (150 mM NaCl, 0.005% (v/v) Tween-20, 25 mM Hepes, pH 7.4) and analysed at 25 °C. For each determination, 350 nM GpIb α was injected at a flow rate of 5 μ l/min for 4 minutes (yielding 500 RU, 15 fmol/mm²), followed by a 2 minute association phase by injection of vWF- or A1 variants (5 – 150nM) at 20 μ l/min and a 5 minute dissociation phase. The sensor-chip was regenerated by injections of 50 mM triethylamine, 10 mM sodium formate pH 2.0 containing 150 mM NaCl and another injection of 50 mM triethylamine. The binding of vWF- and A1-variants to GpIb α was evaluated at five concentrations, each determined in triplicate, and analysed with Bia-evaluation software (Biacore AB, Uppsala Sweden) using a 1:1 Langmuir model with baseline drift to compensate for the slow dissociation of GpIb α from 2D4. Binding to GpIb α coated channels was corrected for binding to non-coated channels.

Crystallisation and data collection

A1 crystals were obtained using the hanging-drop vapour-diffusion method at 4 °C. Small differences in the composition of the precipitant solution resulted in different crystal forms (Table I). Micro-seeding was used to increase crystal-size. The dimensions of the crystals used for data collection ranged from 50 to 200 µm. Crystals were equilibrated in precipitant solution containing 30 – 35 % glycerol and flash-cooled in liquid nitrogen. X-ray diffraction data were collected at the ESRF synchrotron-radiation facility, beam lines ID14-EH2, ID14-EH3 and ID9 (Grenoble, France). Data reduction, merging and scaling were performed with DENZO and SCALEPACK²⁰. Diffraction data statistics are summarised in table I.

Structure Determination and Refinement

Structures were solved by molecular replacement using CNS²¹ with wt-A1²² as a search model. For model refinement, cycles of rebuilding using O²³ and positional and B-factor refinement using CNS were performed until convergence. In some cases non-crystallographic symmetry restraints were applied, but only in the initial stages of refinement. Cross validation was used throughout refinement using a 5% test set of reflections. Refinement used the maximum-likelihood algorithm²⁴ and bulk-solvent correction was applied. Water molecules were placed in difference electron-density peaks with a peak height of at least 3.0 σ , a distance of 2.7-3.2 Å to a hydrogen-bond donor or acceptor. Water molecules with a B-factor above 100 Å² were rejected. Refinement statistics are summarised in table I.

Strong positive electron density peaks observed in A1 structures wt-P4₁2₁2, wt-P2₁, RQ-P4₁2₁2 and RQ-P4₃2₁2 were interpreted as cadmium and chloride ions based on peak height and chemical environment (Table I). The cadmium ions mediate important crystal contacts, since crystals that were transferred to EDTA-containing precipitant solution dissolved.

^f Structures have been deposited at PDB accession numbers aaa, bbb, ccc, respectively.

^g When more than one model is observed in the asymmetric unit, the models are indicated by characters between parenthesis.

Results and Discussion

Local structural effects of mutation Arg543Gln in A1

The process of A1 activation that results in binding to GpIb α is a poorly understood process. Activation of A1 can be induced by vWD type 2B mutations. In this study we investigated structures of wild type and 2B mutant Arg543Gln-A1 and analysed conformational changes. Both wt- and Arg543Gln-A1 crystallised in three different crystal forms, depending on small differences in crystallisation conditions. X-ray diffraction data were collected to a resolution limit ranging from 1.9 to 2.6 Å and the structures were determined by molecular replacement. Crystallographic and refinement statistics are summarised in table I. As it turned out several crystal forms contain multiple A1 domains in the asymmetric unit yielding a total of 6 atomic models of wt-A1 and five atomic models of Arg543Gln-A1.

The overall structure of all eleven A1 domains determined by us are similar to published structures of A1^{13; 14; 22; 25} and consists of a central six-stranded β -sheet flanked on each side by three α -helices. The N- and C-terminal regions of the domain are connected by a disulphide bond between Cys⁵⁰⁹ and Cys⁶⁹⁵. We will refer to the Cys⁵⁰⁹-Cys⁶⁹⁵ loop structure as the body of the domain while the residues on either side of the disulphide-bonded loop will be called the N- and C-terminal flanking peptides.

VWD type 2B mutation Arg543Gln strongly activates vWF¹⁶. Residue Arg⁵⁴³ is located at the end of α -helix 1 close to the bottom face of the domain (figure 1A). Replacement of Arg⁵⁴³ by glutamine does not change its backbone conformation. In the mutant the glutamine side chain points in a different direction and interacts with residues Arg⁶⁸⁷ and Asp⁶⁸⁸. As a consequence, the conformation of these residues and nearby residues Asp⁵³⁹ and Met⁵⁴⁰ changes slightly, the largest shift being 1.9 Å for the side-chain of Met⁵⁴⁰. In five of the six wild-type structures the head-group of Arg⁵⁴³ packs against one face of the five-membered ring of the His⁵⁰⁵ side-chain providing favourable van der Waals interactions. This interaction with His⁵⁰⁵ is not possible in the mutant. In four of the five mutant structures His⁵⁰⁵ undergoes a large shift. This shifted conformation is also observed in one wild-type structure. In one mutant structure His⁵⁰⁵ shifts only slightly, but a hydrogen bond to Glu⁵⁴² that is observed in the wild-type structures, is lost. Thus, mutation Arg543Gln destabilises two types of interactions of His⁵⁰⁵ namely van der Waals interactions with the arginine side chain and, indirectly, hydrogen bonding to Glu⁵⁴².

Figure 1: Conformations of the N- and C-terminal flanking peptides. Superposition of different A1 models that are colour coded as follows: wild-type A1, *green*; Arg543Gln-A1, *blue*; A1•GpIbα, *red*. A) Stereographic representation of the A1 domain local to Arg⁵⁴³. In wt-A1 Arg⁵⁴³ forms tight van der Waals interactions with His⁵⁰⁵ that is directed in an ideal orientation for hydrogen-bond formation with Glu⁵⁴². In 2B-A1 the side chain of Gln⁵⁴³ is shorter and the polar head-group is now oriented to the interior of the domain. This has no effect on the conformation of the local main-chains, but induces small shifts in the side chains of Met⁵⁴⁰, Arg⁶⁸⁷ and Asp⁶⁸⁸. Moreover, the orientation of the Gln⁵⁴³ side chain abolishes the positioning of His⁵⁰⁵ to Glu⁵⁴². B) Stereographic representation of a part of the lower half of the A1 domain

showing long-range effects of mutation Arg543Gln. In six of the seven wt-A1 models the N-terminal flanking peptide adopts the shielded conformation and forms many interactions with the body of the domain (see table III). In three out of four Arg543Gln models and in A1•GpIbα the N-terminal flanking peptide adopts the unshielded conformation. The C-terminal flanking peptide adopts the shielded conformation only in three wt-A1 models. Several residues in the body of A1 that interact with the N- and C-terminal flanking peptides are subjected to type 2B mutations. The shielded conformation of the N- and C-terminal flanking peptides suggest that they block the GpIbα binding site in multimeric vWF.

In the shielded conformation of the N-terminal flanking peptide, Pro⁵⁰³ stabilises the conformation of Tyr⁵⁰⁸ that directly interacts with loop α1β2. Therefore loop α1β2 may be less stable in the unshielded conformation (as observed by the significant movement of Tyr⁵⁰⁸), but it does not adopt a different conformation. This suggests that GpIbα may induce a conformational change in the loop. The diagrams were generated with MOLSCRIPT³⁴ and RASTED3D³⁵

Structural comparison of A1 structures

To analyse the occurrence of long range conformational changes in A1 induced by vWD type 2B mutations we compared all wild-type and mutant crystal structures currently available. In addition to the five wild-type and six mutant structures determined in this study, the comparison included a model of Arg543Gln-A1 from the A1•GpIbα complex¹³, the structure of wild-type A1 published by Emsley *et al.*²² and structures of wild-type A1 and A1 mutant Ile546Val published by Celikel *et al.*^{14; 25}. The latter two structures of A1 were crystallised in complex with a Fab-fragment of function inhibiting antibody NMC-4 and lack the N-terminal flanking peptide up to residue 508.

Pair wise superposition of all free A1 models (Table II, first three columns) shows no conformational changes in the α -helices and β -strands, indicating that conformational changes as observed in the α_2 I-domain after collagen binding ²⁶ do not occur in A1 containing a type 2B mutation. Within the body of A1 considerable variation is observed for several loops. However, differences among wild-type models and among mutant models are similar in magnitude as differences between wild-type and mutant models. This suggests that the variation in these loops is due to inherent flexibility and is not a consequence of the mutation. Also comparison of A1•GpIb α with free wt- or mutant A1 structures shows significant differences for the body of the domain, *i.e.* the disulphide bond, loop $\alpha 1\beta 2$ and hairpin $\beta 2\beta 3$ (Table II, last two columns). The latter two regions interact directly with GpIb α . However, the differences between wt-A1 and A1•GpIb α are not larger than differences between type 2B A1 and A1•GpIb α . This suggests that these differences are introduced by GpIb α binding and not by the mutation.

^a Root mean square deviation in positions (r.m.s.d.) values were calculated using the program LSQMAN ³³. Values (*black*) for the mobile loops are given when the r.m.s.d. for the loop was 1.5 fold increased compared to the overall r.m.s.d.. Not significant values are given in *grey*.

The most prominent structural variation is observed in the flanking peptides. For the N-terminal flanking peptide the root-mean-square deviation in the position of the individual peptides (r.m.s.d.) between wild-type models is significantly smaller than the difference between wt- and 2B A1. Thus for the N-terminal flanking peptide the variation is correlated with the presence of a type 2B mutation. The variation seems not to be correlated for the C-terminal flanking peptide. The differences in the N- and C-terminal flanking peptides in the A1•GpIb α complex is larger than differences among free wt- and free 2B A1 models. This suggests that GpIb α binding to A1 induces additional conformational changes in the N- and C-terminal flanking peptides.

The conformation of the flanking peptides

Conformations of the N-terminal flanking peptides can be divided in two groups based on the observed main-chain conformation at Asp⁵⁰⁶. In the first group the peptide makes a 90° turn at Asp⁵⁰⁶ and folds over the body of the domain (figure 1B). In this conformation Asp⁴⁹⁸ approaches the GpIb α -binding site at the bottom of A1 within 7 Å. Although this residue itself does not overlap the GpIb α -binding site, one or two additional residues may be sufficient to do so. This conformation will be referred to as the shielded conformation. The shielded conformation dominates in the wild-type structures. It is observed in six out of seven models of wt-A1 and in only one model of Arg543Gln-A1. In the alternative 'open' conformation the N-terminal flanking peptide makes a turn in the opposite direction at Asp⁵⁰⁶ and points away from the GpIb α -binding site. This conformation is observed in three out of four models of Arg543Gln-A1 and in one model of wt-A1. In the open conformation the N-terminal flanking peptide has few interactions with the body of the domain. As a consequence the peptide is more flexible: on average fewer residues are visible in the electron density and the r.m.s.d. is large compared to the shielded conformation (1.73 Å for the open conformation and 0.89 Å for the shielded conformation). The shielded conformation of the N-terminal flanking peptide is stabilised via multiple interactions with the body of the domain (figure 1B, table III). Many of the residues involved in these interactions, either located in the flanking peptide or in the body of the domain, are subject to vWD type 2B mutations. In the A1•GpIb α complex the N-terminal flanking peptide adopts the open conformation. However, its conformation differs from other open conformations, due to an additional shift of the disulphide bond and a concomitant movement of Tyr⁵⁰⁸. Therefore, binding of GpIb α to A1

involves additional conformational changes that are not induced by the type 2B mutations studied here.

n.d.; not described in literature.

^a The phenotype has been assigned although the effect of the mutation was studied in a vWF-variant containing more than one mutation.

The C-terminal flanking peptide protrudes like a stalk from the bottom of A1 (figure 1B). The conformation can roughly be divided in two groups depending on the orientation of the main chain at Glu⁷⁰⁰. In one group, containing three wild-type and one 2B structure, residues Pro⁷⁰² and Pro⁷⁰³ are within 2 and 3 Å, respectively, of the GpIb α -binding site. This

would block GpIb α binding. In analogy to the N-terminal flanking peptide we call this the shielded conformation. In the other conformation, observed in five wt-A1 models and all but one model of mutant A1, the C-terminal flanking peptide is located further away from the GpIb α -binding site due to a rotation of 180 degrees around the Glu⁷⁰⁰ peptide bond. In the A1•GpIb α complex an open conformation is observed.

Since the closed conformation of the N- and C-terminal flanking peptides is observed predominantly, but not exclusively, in free wt-A1 and the open conformation in Arg543Gln-A1, it suggest that both conformations exists in wt-A1 and mutant A1, but that a type 2B-mutation shifts the equilibrium to the open conformation.

The conformation of loop $\alpha 1\beta 2$

Loop $\alpha 1\beta 2$, comprising residues Ile⁵⁴⁴ to Trp⁵⁵⁰, occupies a central position at the bottom face of the domain. In the shielded conformation this loop contacts the N- and C-terminal flanking peptides via a tight stacking of the side chains of residues Pro⁵⁰³, Tyr⁵⁰⁸, Arg⁵⁴⁵ and Trp⁵⁵⁰, and a looser interaction with Ala⁷⁰¹ (figure 1B). These residues, except Tyr⁵⁰⁸ of which no data are available, are subject to vWD type 2B mutations (Table III). In the A1•GpIb α complex the conformation of loop $\alpha 1\beta 2$ is different compared to the conformation in wt-A1. In addition, loop $\alpha 1\beta 2$ in the complex is mobile and interacts directly with GpIb α , suggesting that it is involved in activation. However, the conformation of loop $\alpha 1\beta 2$ in wt-A1 and 2B-A1 is similar, indicating rather an indirect than a direct role in activation.

The conformation of hairpin $\beta 2\beta 3$

A closer look at hairpin $\beta 2\beta 3$ (residues 551-566) was prompted by the hypothesis formulated by Celikel *et al.* that mutation Ile546Val induced a conformational change 28 Å further in the domain in hairpin $\beta 2\beta 3$ resulting in a higher affinity for GpIb α ¹⁴. Our comparison of a much larger set of structures now shows that hairpin $\beta 2\beta 3$ adopts a range of conformations (Table II). Part of the observed variability of $\beta 2\beta 3$ is accounted for binding of cadmium and chloride ions to residues Glu⁵⁵⁷, His⁵⁵⁹, Asp⁵⁶⁰, and His⁵⁶³ in several of our structures (Table I) and in the structure of Emsley *et al.*²². A superposition of all models not affected by ion binding (figure 2) stills shows substantial variation in the conformation of $\beta 2\beta 3$, in particular for main-chain and side-chain atoms of residues Asp⁵⁶⁰, Gly⁵⁶¹, Ser⁵⁶², His⁵⁶³. However, the conformation of $\beta 2\beta 3$ in the Ile546Val- and Arg543Gln-A1 mutants is different from the conformation observed in the A1•GpIb α complex. Clearly, hairpin $\beta 2\beta 3$ is inherently flexible

and its conformation as observed in the structure of type 2B mutants is not a high-affinity state of the A1 domain. Alternatively, the 2B phenotype of the Ile546Val mutant may involve a conformational change in the N-terminal flanking peptide. However, this could not have been observed in the crystal structure of Ile546Val-A1, since the construct used for crystallisation did not contain the N-terminal flanking peptide.

Figure 2: Conformations of hairpin $\beta 2\beta 3$. Superposition of A1 models wt-P2₁₂₁₂₁, green, wt-loak, dark grey, RQ-P2₁₂₁₂₁, blue, IV-1fns, light grey, and A1•GpIb α , red. The conformation of hairpin $\beta 2\beta 3$ in the two wt-A1 models are not identical but differ at residues Asp⁵⁶⁰, Ser⁵⁶² and His⁵⁶³. In addition, the conformation in two vWD type 2B A1 variants of A1 are not similar at these residues and do not resemble the conformation of the hairpin in the A1•GpIb α complex that contains by definition the active conformation.

Binding of the A1 domain and vWF to GpIb α

To investigate if GpIb α binding to the A1 domain is similar as to vWF, we analysed GpIb α -binding by SPR. These results have been summarised before¹³, but will be discussed here in detail. Wild-type vWF did not spontaneously bind to GpIb α up to a concentration of 150 nM, but Arg543Gln-vWF did (figure 3). In contrast, wt-A1 bound spontaneously to GpIb α with an affinity of 27 nM. Therefore the wt-A1 domain is already activated. Mutation Arg543Gln in the A1 domain reduced the K_D only 3 fold showing that the effect of the mutation is subtle in A1⁴⁹⁸⁻⁷⁰⁵. This observation is in agreement with our crystallographic data, since we observed that only the C-terminal flanking peptide partially overlaps the GpIb α binding site at the bottom of A1. The N-terminal flanking peptide in A1⁴⁹⁸⁻⁷⁰⁵ approaches, but does not overlap this GpIb α binding site and is therefore not able to prevent GpIb α binding. Probably additional elements in the flanking peptides outside residues 498-705 are required to keep A1 in a low-affinity state as has been demonstrated for other shorter and longer A1-constructs²⁷;

28;29;30. Most likely the N- and C-terminal flanking peptides act in concert, because only

simultaneously deletion of the peptides in vWF result in activation ³¹.

Figure 3: Binding of multimeric vWF and the isolated A1 domain to immobilised GPIIb α was analysed by surface plasmon resonance in a Biacore system. Wild-type A1 bound spontaneously to GPIIb α , K_D 27 nM, and mutation Arg543Gln increased the affinity for GPIIb α three fold. Wild-type vWF did not bind to GPIIb α , suggesting a K_D of at least 5 μ M. Mutation Arg543Gln in multimeric vWF induced spontaneous binding.

Conclusion

We have investigated structures of wt- and type 2B mutants A1 in relation to GPIIb α binding. Conformational changes induced by type 2B mutations within the body of the A1 domain were not observed. However, conformational changes were observed for the N- and C-terminal flanking peptides. In wt-A1 the peptides are directed to the GPIIb α binding site at the bottom of A1, suggesting that these peptides overlap the binding site in vWF. In type 2B A1 the peptides are directed differently and probably do not overlap the binding site in type 2B vWF. The importance of the N- and C-terminal flanking peptides in vWF-activation is underlined ristocetin, which interacts with the N- and C-terminal flanking peptides ^{9; 32}. Ristocetin-induced activation resembles shear-induced activation ¹².

Our crystallographic analysis supports a mechanism for activation of vWF as depicted in figure 4. In normal circulation the N- and C-terminal flanking peptides shield the GPIIb α – β -finger binding site at the bottom of A1 and vWF has a low-affinity conformation. Pathological shear forces acting on vWF in occluded arteries or drag forces generated by the blood flow acting on immobilised vWF pulls the flanking peptides away by a hinge motion at residues Asp⁵⁰⁶ and Glu⁷⁰⁰ that exposes the GPIIb α binding site. VWD type 2B mutations

likely affect the equilibrium between the shielded and open conformation and switch vWF from the low- to the high-affinity state.

Figure 4: Mechanism of vWF-A1 activation. In vWF both the N- and C-terminal flanking peptides shield the GpIb α – β -finger binding site and vWF adopts its low-affinity state. Due to shear activation or a vWD type 2B mutation, the N- and C-terminal flanking peptides are rotated around a hinge (Asp⁵⁰⁶ and Glu⁷⁰⁰, respectively, indicated by the blue circles). This opens the GpIb α -binding site and switches A1 to the high-affinity state.

Chapter 7

General discussion

Haemostatic plug formation at sites of vascular injury is required to stop bleeding. This process is started by platelet adhesion and aggregation and is followed by fibrin formation. Platelet adhesion and aggregation requires the subendothelial matrix, von Willebrand Factor (vWF), platelet receptors glycoprotein (Gp) Ib-IX-V complex, GpVI, integrins $\alpha_2\beta_1$, $\alpha_{2b}\beta_3$ and fibrinogen.

Adhesion of platelets at sites of vascular damage is initiated by binding of the vWF A3 domain to the subendothelial matrix, followed by rolling and tethering of platelets over this immobilised vWF. The latter process requires the A1 domain of vWF and GpIb α on the platelet. Rolling reduces the velocity of the platelets, a process that is also mediated by GpVI and integrin $\alpha_2\beta_1$. Now the platelets become firmly attached and activated. This allows additional platelets to interact with these initial immobilised platelets; the process of thrombus growth is initiated. Platelet-platelet interactions within the thrombus are mediated by the GpIb-IX-V complex, integrin $\alpha_{2b}\beta_3$ and vWF and fibrinogen. Finally fibrinogen is converted to fibrin, giving the haemostatic plug its final strength.

Von Willebrand Factor is stored in specific organelles in platelets and endothelial cells and it circulates free in plasma. Because vWF and platelets both circulate free in plasma, vWF should not bind spontaneously to platelets. To this end, vWF needs to be activated. The activation mechanism is not understood, but activation can be achieved in several ways.

- 1) Binding of vWF to the subendothelial matrix, in particular to collagen ¹.
- 2) Binding of exogenous ligands to vWF, for example the antibiotic ristocetin-A ² or snake toxins botrocetin ³ or bitiscetin ⁴.
- 3) Von Willebrand Disease (vWD) type 2B mutations in the A1 domain ⁵.
- 4) Platelet-type vWD mutations in GpIb ⁶.

The studies in this thesis were conducted to investigate the above processes. In particular, we investigated at a molecular level (i) the binding of the A3 domain to collagen type III, (ii) the structure of the A1•GpIb α complex and (iii) conformational changes that activate the A1 domain for binding to GpIb α .

Binding of vWF to collagen.

Insight at the molecular level how vWF immobilises platelets on the subendothelial matrix may be useful to develop new anti-arterial thrombotic compounds. To this end, we investigated the interaction of the A3 domain with collagen type III. These results are described in **chapters 2, 3 and 4**. Based on the homology with integrin I-domains, which bind collagen at the top-face of the domain, several groups, including ours, have introduced mutations at the top face of A3. However, these mutations did not reduce collagen binding suggesting that the collagen-binding site in A3 should be located somewhere else. To obtain information about the approximate location of the collagen-binding site, we solved the crystal structure of the A3 domain in complex with a Fab fragment of function inhibiting antibody, RU5 (**chapter 2**). We identified the RU5-epitope at the front- and bottom face of A3. Subsequent mutations introduced in and around the RU5 epitope indeed resulted in a reduced collagen-binding. The collagen-binding site in A3 has now been mapped solely to the front face of the domain. Based on the quantitative effects of the mutations in collagen binding, we hypothesise that residues in the lower part of the collagen-binding site are essential in collagen binding, whereas residues in the upper part are involved but not essential in collagen binding. Since the collagen-binding site in the A3-domain contains negatively charged and hydrophobic amino-acid residues, it is evident that A3 binds to positively charged and hydrophobic residues within a collagen triple-helix. The front face of the A3 domain is rather flat and specific collagen sequences that bind to vWF are unknown. Therefore an automated procedure to dock a collagen molecule failed. Manually we identified a range of orientations of the engagement of a collagen triple helix on the A3 domain (figure 1).

Figure 1: Binding-orientations of a collagen triple helix to the vWF-A3 domain. The front-face of the A3 domain is shown. Residues in *magenta* are essential in collagen binding, residues in *green* are involved but not essential in collagen binding, and residues in *yellow* are not involved at all. The collagen molecule is close to Pro⁹⁸¹, shown in *red*, but does not interact with it. Two collagen molecules that enclose the range of orientations for the A3-collagen interaction are shown and the angle is indicated by the arrows.

Schneppenheim *et al.* described several patients with a mutation in the A3 domain that inhibited collagen binding in a solid-state collagen-binding assay⁷. Surprisingly, the patients

are without bleeding problems. However, the mutated residues co-localise with the region of A3 that is involved, but not essential for collagen binding. On the other hand, mutations in the region that is essential in collagen binding may give bleeding problems, but these mutations are not yet identified in patients.

Ribba *et al.* described two related patients suffering from mild bleeding problems, with a mutation in the A3 domain ⁸. Residue Ser⁹⁶⁸ is mutated to threonine. Ser⁹⁶⁸ is not solvent exposed, but is buried under the collagen binding site. Therefore a direct effect in collagen binding seems unlikely. In the study described in **chapter 4** we solved the crystal structure of A3 with this mutation. Interestingly, we did not observe any conformational changes in A3. As we have described in chapter 2, two loops at the lower part of the front face of A3 are rather mobile, suggesting an induced-fit model for the binding of A3 to collagen. Ser⁹⁶⁸ is close to one of these loops and we hypothesised that the mutation shifts the equilibrium to the low-affinity conformation and thereby reduces the affinity of A3 for collagen.

For the α_2 -I domain it has been shown that collagen binding induces conformational changes within the domain. To investigate if conformational changes occur in A3 upon collagen binding, co-crystallisation experiments should be performed of A3 in complex with a short collagen-triple helix. However, it is still not known which collagen sequence (and probably it is not a single sequence but multiple) binds to A3 with high affinity. This may be investigated by several approaches: (i) monoclonal antibodies raised against collagen type III may inhibit binding of vWF to collagen. Via phage-display-technology the epitope of the antibody can be determined, (ii) cross-linking of collagen-bound vWF and subsequent digestion of the vWF-collagen complex. Via N-terminal protein sequencing the specific collagen sequences may be identified.

It has been argued that *in vivo* the A3 domain is not involved in immobilizing platelets to the vessel wall, because patients with a mutation in the collagen-binding site do not have a bleeding problem ⁷. However, we have shown that these mutated residues are located in the upper part of the collagen-binding site that is involved, but not essential in collagen binding. Recently the relevance of the binding of A3 to collagen *in vivo* has been demonstrated by injection of monoclonal antibodies directed against the A3 domain in baboons ⁹. This resulted in an elongated bleeding time. To tackle these discrepancies further, bleeding-time experiments in vWF knock-out mice should be performed after infusion with either mouse wild-type vWF or mouse vWF lacking the A3 domain.

The A1•GpIb α complex and conformational changes in A1.

VWF becomes activated when it is immobilised to a surface. As mentioned above, the activation-mechanism is not understood. Most likely it requires conformational changes in the A1 domain. It is generally believed that these conformational changes are similar to the conformational changes induced by vWD type 2B mutations.

To address this problem we solved a crystal structure of GpIb α and of GpIb α in complex with the A1 domain (**chapter 5** and figure 2). The leucine-rich repeats of GpIb α adopt a horse-shoe like structure that is sandwiched on either side by flanking elements. The N-terminal flanking structure contains the so-called β -finger that protrudes from the domain. The C-terminal flanking structure contains the so-called β -switch, which is structurally disordered, and is followed by the anionic region. In the A1•GpIb α complex we identified two sites in A1 that tightly interact with GpIb α . The first interaction site is at the upper part of A1 and involves residues of hairpin $\beta 2\beta 3$ and nearby residues. This interaction site binds to the GpIb α – β -switch and several other GpIb α residues in the vicinity of the β -switch. When the β -switch interacts with the A1 – $\beta 2\beta 3$ hairpin, the β -switch undergoes a conformational change and adopts a β -hairpin conformation. Since platelet-type vWD mutations are located in the β -switch and involve mutations that favour β -strand formation, it is likely that these mutations induce the β -hairpin structure in the β -switch and thereby activate GpIb α . The second GpIb α binding site in A1 is located at the lower part of the domain, close to the region in A1 that contains the type 2B mutations. This region interacts with the GpIb α β -finger.

Figure 2: Crystal structure of the A1•GpIb α complex. A1 is shown in *blue* and GpIb α is shown in *red*. GpIb α has two main interaction sites within A1. The β -finger interacts with several loops, including loop $\alpha 1\beta 2$, at the bottom of A1. The β -switch interacts with strand $\beta 3$ of hairpin $\beta 2\beta 3$ and several other residues at the top of A1. Several long-range charge-charge interactions between the GpIb α LRRs and the body of A1 provide an additional interaction site.

In the past, two structures of wt-A1 and one structure of vWD type 2B mutant Ile546Val have been published¹⁰⁻¹². In the study described in **chapter 6** we solved the structure of three different crystal forms of wt-A1⁴⁹⁸⁻⁷⁰⁵, yielding six models, and three different crystal forms of type 2B mutant Arg543Gln-A1, yielding five models. In all wt- and type 2B A1 models the overall fold of the body of the domain was similar. In contrast, the N- and C-terminal flanking peptides adopted a different conformation in type 2B mutant Arg543Gln-A1 compared to the conformation in wild-type A1. In most of the wt-A1 models the N- and C-terminal flanking peptides are directed towards the GpIb α – β -finger binding site suggesting that in multimeric vWF they overlap with the β -finger binding site. This is the so-called shielded conformation. In most of the Arg543Gln-A1 models the N- and C-terminal flanking peptides are pointed in a different direction due to a hinge motion around Asp⁵⁰⁶ and Glu⁷⁰⁰, respectively, thereby opening the β -finger binding site. This motion of the flanking peptides could activate the A1 domain for GpIb α binding. It is likely that shear activates A1 via a similar mechanism, because vWF that is immobilised via its A3 domain may “sense” the forces generated by the flowing blood. As a result, vWF may partially unwind that induces the conformational change in the N- and C-terminal flanking peptides of the A1 domain.

Figure 3: Schematic representation of A1 activation. In inactive vWF the N- and C-terminal flanking peptides of A1 fold over the body of the domain and shield the β -finger binding site. Activation induces a motion around two hinges (indicated by the *blue circle*) that opens the binding site.

Based on our observations we disagree with the hypothesis of Celikel *et al.*¹² who postulated that A1 is activated due to a conformational change in the $\beta 2\beta 3$ hairpin of A1. In our structural analysis we observed conformational flexibility of hairpin $\beta 2\beta 3$ that is not correlated with the presence of a type 2B mutation. Celikel *et al.* were not able to observe a conformational change in the N-terminal flanking peptide, because these residues were absent in their A1-construct.

The exact number of residues in the N- and C-terminal flanking sequences that are required to prevent spontaneous GpIb α -binding is still unknown. Residues upstream of Asp⁴⁹⁸

and downstream of Thr⁷⁰⁵ are required to suppress GpIb α binding, because various A1-constructs with longer N- and C-terminal flanking peptides do not bind spontaneously to GpIb α , whereas A1⁴⁹⁸⁻⁷⁰⁵ does. It is also known that *O-linked* glycan residues are required to prevent spontaneous GpIb α binding, because non-glycosylated (*i.e.* bacterial) or desialated A1 fragments bind spontaneously to GpIb α , whereas identical glycosylated A1 fragments do not. It is, however, still not known which residues require *O*-glycosylation. To address the above problems, an A1-construct should be developed that is fully glycosylated and does not bind spontaneously to GpIb α . Next, the number of residues in the N- and C-terminal flanking peptides should be systematically decreased and *O-linked* glycosylation sites should be specifically removed. Additionally, the A1 construct which does not interact spontaneously with GpIb α should be crystallised to study the interactions of the N- and C-terminal flanking peptides with the body of the domain at a molecular level.

Binding of vWF to a surface like glass, collagen or endothelial cell matrix triggers binding of GpIb α on the platelet to vWF. As is described in chapters 5 and 6, activation of vWF involves conformational changes in the N- and C-terminal flanking peptides of the A1 domain. These conformational changes may be induced by binding of the A3-domain to collagen, or by hydrodynamic forces generated by the flowing blood. In addition, it can not be excluded that GpIb α mediated binding of platelets to immobilized vWF is an effect of the increased local vWF concentration. Therefore Biacore-experiments should be performed at multiple flow-rates in which different vWF-densities are immobilised via collagen or via a monoclonal antibody to the sensor chip.

In summary, our investigations identified the collagen-binding site on the vWF-A3 domain. Based on the surface characteristics of the collagen-binding site, a hypothesis of the nature of the collagen triple helix to which A3 will bind has been made. The identification of specific collagen sequences that interact with A3 is subject for future research. Crystal structures of GpIb α , A1•GpIb α , wt- and R543Q-A1 have been solved. Based on these structures we hypothesised that the N- and C-terminal flanking peptides of A1 shield one of the two GpIb α binding sites in A1 and thereby prevent GpIb α binding. A1-activation involves a conformational change in these flanking peptides. The exact number of residues in the N- and C-terminal flanking peptides that shield A1 completely is subject for further research.

In conclusion, we have gained insight in the collagen-vWF-GpIb α interactions at a molecular level. It has not escaped our notice that these results are of significant value for the development of new drugs against arterial thrombosis.

Hoofdstuk 8

Samenvatting in het Nederlands

Inleiding

Het stoppen van een bloeding bestaat uit twee processen: bloedstelping en bloedstolling. Tijdens de bloedstelping worden bloedplaatjes aan de beschadigde vaatwand gebonden en ontstaat de plaatjesprop. Bloedstolling is het proces van fibrinevorming, dat de plaatjesprop zijn uiteindelijke sterkte geeft. Het in dit proefschrift beschreven onderzoek betreft een onderdeel van de **bloedstelping**.

Binding van bloedplaatjes aan een beschadigde vaatwand is een complex proces en is afhankelijk van componenten uit de vaatwandmatrix, waaronder collageen, verschillende receptoren op het bloedplaatje, waaronder GpIb-IX-V, GpVI, $\alpha_2\beta_1$ en $\alpha_{2b}\beta_3$, en plasma-eiwitten zoals von Willebrand factor en fibrinogeen. In dit proefschrift worden onze studies naar **Von Willebrand factor** beschreven.

Von Willebrand factor, vWF, is een multimeer eiwit dat aan collageen op de plaats van de beschadiging in de vaatwand bindt. Vervolgens vinden er veranderingen in de structuur van vWF plaats waardoor vWF ook aan receptor GpIb-IX-V op het bloedplaatje kan binden. Nu is het bloedplaatje geïmmobiliseerd op de plaats van de beschadigde vaatwand. De binding tussen het geïmmobiliseerde bloedplaatje en de vaatwand wordt versterkt door interacties van plaatjes receptoren GpVI en $\alpha_2\beta_1$ met collageen. Vervolgens binden andere bloedplaatjes aan de eerste laag plaatjes via interactie van plaatjes receptor $\alpha_{2b}\beta_3$ met fibrinogeen en vWF uit het plasma en ontstaat de plaatjesprop. **De binding van vWF aan collageen en GpIb-IX-V** zijn de specifieke onderwerpen van dit proefschrift.

Resultaten

In **hoofdstuk één** wordt een algemene inleiding over bloedstelping gegeven. Primair wordt de aandacht gelegd op **von Willebrand Factor** (vWF). Beschreven wordt hoe en waar vWF gesynthetiseerd wordt en waar het gelokaliseerd is in het lichaam. Verder wordt beschreven uit welke domeinen vWF is opgebouwd en wat de functie deze domeinen is. Specifiek wordt ingegaan op de A1 en A3 domeinen.

In **hoofdstuk twee en drie** zijn de experimenten beschreven waarmee de collageen bindingsplaats op het A3 domein is gelokaliseerd. In analogie met homologe I-domeinen, die

collageen binden aan de bovenkant van het domein, waren in het verleden aan de bovenkant van het A3 domein mutaties geïntroduceerd. Echter, collageen binding van deze mutanten was normaal waardoor geconcludeerd kon worden dat collageen niet aan de bovenkant van A3 bindt. Om de collageen bindingsplaats op het A3 domein grof te bepalen hebben we de kristal structuur van A3 in complex met het Fab-fragment van monoclonaal antilichaam RU5 bepaald. RU5 remt de binding van vWF aan collageen waardoor het waarschijnlijk is dat het epitoop van RU5 en de collageen bindingsplaats (partieel) overlappen. In de kristal structuur van het A3•RU5 complex was duidelijk dat RU5 aan de voor- en onderzijde van A3 bindt en niet aan de bovenkant. Op basis van deze structuur hebben we 27 aminozuren geïdentificeerd die betrokken zouden kunnen zijn in collageen binding. Deze aminozuren hebben we gemuteerd. Een aantal van deze mutanten bezit een verlaagde affiniteit voor collageen, wat inhoudt dat de gemuteerde aminozuren zeer waarschijnlijk betrokken zijn bij de collageen binding. Op basis hiervan hebben we geconcludeerd dat de collageen bindingsplaats aan de voorkant van het A3 domein ligt. Uit de experimenten bleek tevens dat de aminozuren in de onderste helft van de collageen bindingsplaats essentieel zijn voor de collageen binding, terwijl aminozuren in de bovenste helft slechts additioneel betrokken zijn. Een hypothetisch model van de binding van collageen aan A3 is gegeven in figuur 1.

Collageen residuen die aan A3 binden zijn nog niet geïdentificeerd. Nu de collageen bindingsplaats op het A3 domein gelokaliseerd is kunnen we op basis van de karakteristieken van de bindingsplaats een uitspraak doen over collageen sequenties die aan A3 binden. Op basis hiervan is het waarschijnlijk dat hydrofobe- en positief geladen collageen sequenties aan A3 binden.

Figuur 1. De collageen bindingsplaats op het vWF-A3 domein. Ruimtelijk model van de voorkant van het vWF-A3 domein. Residuen in *roze*, Asp⁹⁷⁹, Ser¹⁰²⁰ en His¹⁰²³, zijn essentieel voor de collageen binding en residuen in *groen*, Ile⁹⁷⁵, Thr⁹⁷⁷, Val⁹⁹⁷, Glu¹⁰⁰¹ en Arg¹⁰¹⁶, zijn betrokken bij de collageen binding, maar zijn niet essentieel. Residuen in *geel* hebben geen interactie met collageen. Residuen in *grijs* hebben we niet gemuteerd. Pro⁹⁸¹, in *rood*, bindt niet aan collageen, maar als het wordt gemuteerd naar een histidine, remt het de collageen binding via sterische hindering. Twee collageen moleculen zijn weergegeven in blauw en bruin welke de range van mogelijke oriëntaties aangegeven hoe collageen aan A3 kan binden.

Onderwerp voor verdere studie is de identificatie van collageen sequenties die aan A3 binden en het bepalen van de kristalstructuur van een A3•collageen complex.

In **hoofdstuk vier** is de kristal structuur van het A3 domein beschreven dat mutatie Ser968Thr bevat. Deze mutatie is gevonden bij een patiënt met een bloedingsneiging. Aminozuur Ser⁹⁶⁸ is echter niet gelokaliseerd aan het oppervlak van A3, maar net onder de collageen bindingsplaats. Daardoor is een directe rol voor Ser⁹⁶⁸ in collageen binding niet waarschijnlijk. Mutatie Ser968Thr veranderde niet zichtbaar de conformatie van het A3 domein. Echter, uit de vergelijking van vele A3 kristalstructuren bleek dat de collageen bindingsplaats van A3 meerdere conformaties kan aannemen. Hoewel er geen directe experimentele aanwijzingen zijn, veronderstellen we dat een aantal conformaties wel in staat is om collageen te binden en andere conformaties niet. Waarschijnlijk heeft de mutatie invloed op de ratio van de actieve- en de niet-actieve conformatie en wordt het evenwicht verschoven naar de niet-actieve conformatie.

Het A1 domein van vWF bindt aan de receptor GpIb-IX-V op het bloedplaatje. In het onderzoek zoals beschreven in **hoofdstuk vijf** werd de kristal structuur van het A1-bindende deel van GpIb-IX-V, de 290 N-terminale residuen van de GpIb α subunit, bepaald (zie figuur 2). Tevens werd de structuur bepaald van A1 in complex met dit deel van GpIb α . Het vWF-A1 domein heeft twee bindingsplaatsen voor GpIb α . Eén bindingsplaats is gelokaliseerd aan de bovenkant van het A1 domein en bevat aminozuren die op basis van mutatiestudies al eerder waren geïdentificeerd. Dit deel van A1 bindt aan de zogenaamde β -switch op GpIb α . Onverwacht was de tweede bindingsplaats voor GpIb α aan de onderkant van A1 dat interactie heeft met de β -finger van GpIb α . Verder zijn er verschillende lange-afstand lading interacties van residuen in de β -strands van de GpIb α leucine-rich-repeats met A1.

Patiënten met een zogenaamde “Platelet-type von Willebrand Disease” mutatie in GpIb α hebben een bloedingsneiging doordat GpIb α spontaan aan vWF bindt. Hierdoor ontstaan plaatjes-aggregaten die geklaard worden in de milt. De GpIb α en A1•GpIb α -complex structuren verklaren deze spontane vWF-GpIb α interactie. Deze mutaties komen namelijk voor in de zogenaamde β -switch van GpIb α die niet geordend is in vrij GpIb α , maar een β -hairpin conformatie heeft in het A1•GpIb α complex. De mutaties promoten de β -hairpin conformatie waardoor GpIb α spontaan aan A1 kan binden.

Figuur 2. Kristal structuren van GpIbα en A1•GpIbα. De β-switch in vrij GpIbα heeft een wanordelijke structuur. Echter, als GpIbα aan A1 bindt ondergaat de β-switch een conformatieverandering naar een β-hairpin structuur. De β-switch en andere locale GpIbα residuen binden aan de bovenkant van A1. De β-finger bindt aan de onderkant van A1 vlak bij het gebied in A1 waar de activerende 2B mutaties liggen. Residuen in de β-strands van de leucine-rich-repeats van GpIbα hebben lange afstand lading interacties met A1.

In normale situaties bindt het A1 domein van vWF niet spontaan aan GpIbα. Von Willebrand Factor moet eerst worden geactiveerd. Activering vindt plaats doordat vWF aan de vaatwand bindt. Er zijn patiënten met een zogenaamde von Willebrand Disease type 2B mutatie in het A1 domein waardoor vWF spontaan aan GpIbα bindt zonder dat vWF aan de vaatwand gebonden is. Deze patiënten hebben een laag vWF- en plaatjes niveau in hun bloed. Dit leidt tot bloedingen met allerlei complicaties. In **hoofdstuk 6** is deze activering bestudeerd. De kristalstructuren van wild-type A1 en van A1 met type 2B mutatie Arg543Gln werden bepaald. De enige conformatie verschillen werden waargenomen in de flankerende peptiden van A1. In wild-type A1 zijn deze peptiden georiënteerd in de richting van de GpIbα bindingsplaats en overlappen ze waarschijnlijk de GpIbα bindingsplaats in multimeer vWF. In Arg543Gln-A1 hebben de peptiden een andere oriëntatie welke niet kan overlappen met de GpIbα bindingsplaats. Op basis hiervan is de hypothese opgesteld zoals in figuur 3 weergegeven is. Niet geïmmobiliseerd vWF bevat een inactive conformatie doordat de flankerende peptiden de GpIbα bindingsplaats overlappen. Vaatwand-gebonden vWF is onderhevig aan hydrodynamische krachten van de bloedstroom waardoor de flankerende

peptiden van A1 als het ware van het domein worden losgetrokken en de GpIb α bindingsplaats geëxposeerd wordt.

Figuur 3. Activatie-mechanisme van het vWF-A1 domein. In rood is de GpIb α bindingsplaats op A1 weergegeven. In inactief A1 overlappen de flankerende peptiden de GpIb α bindingsplaats. Door activatie worden de peptiden anders georiënteerd door een rotatie om een bepaald residue, aangegeven door de blauwe cirkel, aan de basis van de peptiden. Hierdoor wordt de GpIb α bindingsplaats geëxposeerd en kan GpIb α binden.

Onderwerpen voor verder onderzoek zijn: (i) het minimum aantal residuen in de flankerende peptiden in A1 dat nodig is om spontane GpIb α binding van geïsoleerd A1 te voorkomen en (ii) verdere bestudering van het activeringsmechanisme met als vraagstelling of activering plaats vindt doordat vWF geïmmobiliseerd wordt, of dat collageen conformatie veranderingen induceerd.

Conclusie

Von Willebrand Factor (vWF) is een essentieel eiwit voor de vorming van de haemostatische plug; vWF bindt bloedplaatjes via hun receptor GpIb-IX-V aan collageen op de plaats van vaatwandbeschadiging. Disfunctionering van collageen – vWF – GpIb-IX-V-as kan bloedingsneiging of arteriële trombose tot gevolg hebben. Het onderzoek zoals beschreven in dit proefschrift heeft inzicht verschaft op moleculair niveau in de interacties van vWF met zowel collageen als met GpIb α . Deze gegevens kunnen van belang zijn voor de ontwikkeling van medicijnen tegen arteriële trombose.

Dankwoord

Ziezo, het proefschrift is dan eindelijk klaar.

Daarom wil ik een aantal mensen bedanken die mij al die jaren op het lab. en daarbuiten hebben bijgestaan. Jan Sixma, mijn promotor, bedankt voor alle enthousiasme en kennis die je de afgelopen vier jaren hebt over gebracht. Nu ik – als je laatste AIO – het vWF-project heb afgesloten, kun je rustig van een welverdiende oude dag gaan genieten. Piet Gros, tweede promotor, je bent waarschijnlijk voorlopig nog niet van mij af, want kristallografie is een mooi vak. Eric Huizinga, co-promotor, bedankt voor alle inspiratie en toewijding je mij hebt gegeven. Winnifred Wuyster, dankzij jou zijn hoofdstukken twee en drie mogelijk geworden! Iedereen van lab 1, Marion, Shizuko, Martin IJ, Martin B, Martijn, Douwe, Chantal, Hanneke, Domenico, Ya-Ping, Wilco, lab 2, lab 3, kristallograven, Barend, Lucy, Mitja, Sjors, Classien, Annika, en alle anderen die ik onbewust ben vergeten: jullie waren en zijn fijne collega's.

Verder gaat mijn grote dank uit naar jullie, mijn ouders en schoonmoeder, want jullie hulp was echt geweldig.

Monique, je hebt altijd gezegd dat er meer in het leven is dan wetenschap alleen. Nu mijn proefschrift dan klaar is hebben we daar eindelijk meer tijd voor. Peter, Sander en Pappa is er voor jullie!

Roland

Curriculum vitae

De schrijver van dit proefschrift werd geboren op 12 februari 1971 te Tiel. Het MAVO diploma werd in 1988 behaald aan de Dominicus MAVO te Tiel en het HAVO diploma in 1990 aan de Rijksscholen Gemeenschap eveneens te Tiel. In 1994 werd het HBO-diploma Chemie, afstudeerrichting biochemie, behaald aan de Hogeschool van Utrecht. Tijdens deze studie werd een één-jarige stage volbracht bij Gist-brocades te Delft. Hierna werd de verkorte opleiding scheikunde begonnen aan de Universiteit Utrecht met een biochemisch hoofdvak bij de vakgroep “Centrum voor Biomembranen en Lipide Enzymologie” onder leiding van Prof. Dr. B. de Kruijff. In 1996 werd het diploma behaald.

Van september 1996 tot en met november 1997 was hij werkzaam als analist bij diverse vakgroepen aan de Universiteit Leiden.

Van december 1997 tot en met februari 2002 was hij werkzaam als onderzoeker-in-opleiding bij het Laboratorium voor Thrombose en Haemostase van het Universitair Medisch Centrum Utrecht (onder leiding van Prof. Dr. J.J. Sixma) en de Sectie Kristal- en Structuurchemie van het Bijvoet Centrum voor Biomolecular Research, faculteit scheikunde, Universiteit Utrecht (onder leiding van Prof. Dr. P. Gros) alwaar het in dit proefschrift beschreven onderzoek werd uitgevoerd.

Vanaf maart 2002 werd begonnen aan een project om een assay op te zetten om de activiteit van het von Willebrand Factor cleaving protease in (TTP)-patiënten te bepalen. Dit onderzoek vindt eveneens plaats bij het Laboratorium voor Thrombose en Haemostase.
